Magee, Frederick M. (J'39) (DMOCTY), Ch. Engr., Bellamy-Robie, Inc., 45 Main St., Cambridge; *for mail,* 6 Daniels St., Lexington 73, Mass.
Magee, George Hugh ('21; '35) (FLBK), Gas Engr., L. I. Ltg. Co., 250 Old Country Rd., Mineola; *for mail,* 91 Poplar St., Garden City, N.Y.
Magill, Franklin Robert ('17; '23) (J), Owner, F. R. Magill Co., 1022 Empire Bldg., Pittsburgh 22, Pa.
Maglathlin, Sidney A. ('21; '35), Supt., Engrg. Dept., New England Safety Div., London Guarantee & Accident Co. Ltd., 141 Milk St., Boston 9; *for mail,* 16 Howard St., West Bridgewater, Mass.
Magos, John Peter ('38) (BCSKJ), Dir. of Research, Crane Co., 836 S. Michigan Ave., Chicago 5; *for mail,* 2142 Chestnut Ave., Wilmette, Ill.
Magrath, Howard A. (J'33) (ABNO), Aero. Engr., Army Air Forces, Air Tech. Serv. Comd., TSEAC-5, Wright Field, Dayton; *for mail,* 550 Forest Ave., Dayton 5, Ohio.
Magraw, Lester Andrew ('20) (CMSFKZ), Pres., Dir., Cent. Ill. Pub. Serv. Co., 1228 Ill. Bldg., Springfield, Ill.
Maguire, Edward L. (J'38) (BJM), Mech. Engr., Charge of Estimate & Design Dept., Alloy Fabricators, Inc., 500 Market St., Perth Amboy; *for mail,* Orchard Terrace, Clark Township, N.J.
Maguire, James (J'39) (CDL), Engrg. Dept., Wyeth, Inc., Mason, Ingham Co., Mich.
Maguire, James Henry ('22) (CMJ), Retired; 1739 W. Taylor St., Kokomo, Ind.
Maguire, Jeremiah D. ('11), Pres., Federation Bank & Trust Co., 461—8th Ave., New York, N.Y.
Maguire, Norman Lunny (J'44) (ACMSFE), Aero. Engr., Research Dept., United Aircraft Corp., 400 S. Main St., East Hartford 8; *for mail,* 101 Hope St., Stamford, Conn.
Magura, Milton John (J'41) (KBFS), Assoc. Mar. Engr., U.S. Maritime Comm., 14th & Franklin Sts., Oakland, Calif.
Maguth, Frank J. (J'42), M. J. Maguth & Son, 508 Jefferson St., Carlstadt, N.J.
Magyar, Ernest Alexander (J'40) (EAFKOC), Test Engr., Pratt & Whitney Aircraft Div., United Aircraft Corp., Main St., East Hartford; *for mail,* 46 Congress St., Hartford, Conn.
Maha, Otto Joseph ('44) (NHBJC), V.P., Engrg., Hannifin Mfg. Co., 621 S. Kolmar Ave., Chicago 24, Ill.
Mahaffy, Hugh Morris (J'43) (AMNYOC), Sr. Draftsman, Glenn L. Martin Co., Baltimore, Md.; *for mail,* 1700 Riverview Ave., Wilmington, Del.
Mahaffy, Reid Alexander (J'41) (NJDML), Packaging Engrg. Dept., Union Bag & Paper Corp., 233 Broadway, New York; *for mail,* 209 Clinton Ave., Brooklyn 5, N.Y.
Mahan, Frank Titus, Jr. (J'44) (AMJ), Engr., Aeronca Aircraft Corp., Mun. Airport; *for mail,* 411 Shafor Ave., Middletown, Ohio.
Mahen, Kenneth W. (J'41) (HJL), c/o Hercules Powder Co., Parlin, N.J.
Maher, Robert Lee (J'40) (KLS), Engr., Chase Brass & Copper Co., Waterbury, Conn.; *for mail,* 1418 W. State St., Trenton 8, N.J.
Mahin, Robert Leedy (J'44), Engrg. Dept. Jr. Officer, U.S.N.R., U.S.S. *Shangri-La*, CV-38 F.P.O., San Francisco; *for mail,* Box 137, Route 1, Arvin, Calif.
Mahlab, Salim Saleh (J'42) (DKP), Staff Sgt., Hdq. XXII Corps, G-2 Sec., Ft. DuPont, Del.; *for mail,* 66-01 Saunders St., Forest Hills, L.I., N.Y.
Mahle, Herbert Niedringhaus (J'40) (MJCO), Prod. Engr., Mahle Auto Body Co. Inc., 370 E. 8th St., St. Paul 1, Minn.
Mahon, Buford Milburn (J'37) (HBNJML), Devel. & Design Engr., Simmons Mfg. Co., Ohio St.; *for mail,* 411 E. 4th St., Ashland, Ohio.
Mahon, William Joseph ('24; '34; '35) (CM), Gen. Mgr., Johnson & Johnson de Mex., Apartado Postal 1133, Mexico, D.F., Mex.
Maienknecht, Gaile Edward (J'44) (NKJ), Research Engr., Linde Air Products Co., Tonawanda; *for mail,* 102 Fowler Pl., Kenmore 17, N.Y.
Maier, August R. ('30; '35) (BHECMY), Ch. Engr., Oil Well Supply Co., Colbert Ave., Oil City, Pa.
Maier, Hanns John (J'45), U.S.Navy; 513 Front St., Hempstead, N.Y.
Maier, Harry J. ('45) (BJCSAH), Engrg. Dept., Lunkenheimer Co., Beekman St. & Waverly Ave., Cincinnati 14; *for mail,* 3740 Marydell Pl., Cheviot, Cincinnati 11, Ohio.
Maier, Harry Ludwig, Jr. (J'33) (AKMNTY), Devel. & Design Engr., Natl. Vulcanized Fibre Co., Box 311, Wilmington, Del.
Maier, Michael Walter (J'45), Test Engr., Shock & Vibration Div., Naval Research Lab., Washington; *for mail,* 161—35th St., N.E., Washington; 19, D.C.
Maiersperger, Walter P. (J'39), Maj., Hdq., Air Tech. Serv. Command, Box 1041, Area A, Wright Field, Dayton, Ohio.
Maillard, Albert L. ('25) (CSFKOE), Managing Dir., Elec. League of Indianapolis, Inc., K. of P. Bldg., Indianapolis, Ind.
Mailler, John Preston ('19; '35) (SEHFCD), Ch. Engr., N.J. Power & Light Co., McFarlan St., Dover, N.J.
Main, James M. ('25; '35) (BDHKLS), Mech. Engr., H. K. Ferguson Co., 1650 Hanna Bldg., Cleveland 15; *for mail,* 2347 Valleyview Dr., Rocky River 16, Ohio.
Maine, William Charles (J'36) (FLSTZ), Power Engr., Mohawk Carpet Mills Inc., 57 Lyon St.; *for mail,* 2 McGibbon Ave., Amsterdam, N.Y.
Mainhardt, Robert (J'43) (JYDNA), Engr., U.S. Engrs., Los Alamos; *for mail,* Box 1663, Santa Fe, New Mex.
Mains, William D. (J'38) (KLEY), Ch. Engr., J. C. Mahoney, Inc., 21 West St., New York 6, N.Y.
Mair, Kenneth T. ('30; '35) (CDM), Engr., Am. Terry Derrick Co., South Kearny; *for mail,* 419 E. 7th St., Plainfield, N.J.
Maissian, Edward Daniel (J'38) (HSKA), Lt. Comdr., U.S.N.R., Hull Planning Officer, Naval Shipyard, Terminal Island, San Pedro, Calif.
Majcher, Walter Stanislaus (J'44) (ONEMAJ), Lt. (j.g.), U.S.N., Spec. Projects Officer, U.S.S. *Greyhound*, Pudget Sound Naval Shipyard, Bremerton, Wash.; *for mail,* 1548 S. 5th St., Milwaukee 4, Wis.
Majercik, Anthony S. (J'36) (LBD), Devel. & Mfg. Engr., Teletype Corp., 1400 W. Wrightwood Ave., Chicago 14; *for mail,* 4728½ N. Beacon St., Chicago 40, Ill.
Majneri, Ludwig Anton ('41) (ABHFKC), V.P., Charge of Engrg., Warner Aircraft Corp., 20263 Hoover Ave., Detroit 5, Mich.
Major, Alfred Robert (J'38), Fla. Pulp & Paper Co., Cantonment, Fla.
Major, William S. ('40) (FSEK), Sales Mgr., Power Plant Div., Am. Engrg. Co., Aramingo St., Philadelphia 25; *for mail,* 1415 Edgevale Rd., Philadelphia 31, Pa.
Majors, Harry, Jr. (J'39) (BAHKNY), Instr. in Mech. Engrg., Mass. Inst. of Tech., 77 Massachusetts Ave., Cambridge 39, Mass.
Makasiar, Vincente Valencia ('40) (HBC), Owner, Firm of Vincente V. Makasiar, 205 N. Greene St.; *for mail,* Box 2289, 1004 Jefferson Stand. Bldg., Greensboro, N.C.

Maker, Frank L. ('30) (BK), Designing Engr., Refinery Plants, Stand. Oil Co. of Calif., 225 Bush St., San Francisco; *for mail,* 950 Galindo St., Concord, Calif.

Makhno, Vladimir Victor ('44) (BCKMNO), Mech. Engr., Commonwealth of Australia, 82 Pitt St.; *for mail,* 348 Bronte Rd., Waverly, Sydney, N.S.W., Australia.

Maki, Eino Evert (J'41 (ACMNYB), Mch. Designer, The Celotex Corp., 205 W. Monroe St., Chicago 6; *for mail,* 527 Helmholz Ave., Waukegan, Ill.

Malakoff, Norman H. (J'40) (CKS), 2225½ Linden Ave., Baltimore 17, Md.

Malamut, Martin (J'42) (HSJ), Mech. Engr., Bur. of Ships, Navy Dept., Washington; *for mail,* 247 Delaware Ave., S.W., Washington 4, D.C.

Malany, Herbert Smith ('44) (CSFMK), Steam Serv. Supvr., Westinghouse Elec. Corp., 307 W. 3rd St.; *for mail,* 3855 Hyde Park Ave., Cincinnati 2, Ohio.

Malcolm, Jos. F. (J'37), Chapman Valve Mfg. Co.; *for mail,* 151 Oak St., Indian Orchard, Mass.

Maldari, Carmine Daniel (J'40) (CDM), Lt., Army Air Forces, 120th Base Unit, Sec. K-1, Army Air Base, Richmond, Va.

Male, Reginald LeFleming (J'44) (BHK), Mech. Engr., Gen. Elec. Co., 5 Lawrence St., Bloomfield; *for mail,* Waxberg Lane, Pine Brook, N.J.

Malecki, Myron Benedict (J'43) (CABZ), 4000 E. 74th St., Cleveland 5, Ohio.

Maledy, J. Edward (J'39) (HBE), Maint. Engr., Stand. Oil Co. of Calif., Binxx; *for mail,* 615 D St., Taft, Calif.

Maleev, Vladimir Leonidas ('21) (ENAB), Cons., Research Engr., Harvey Mch. Co., Inc., 6200 Avalon Blvd., Los Angeles 3; *for mail,* 1232 N. Orange Dr., Hollywood 38, Calif.

Malin, Chester George ('40) (MHCO), Cons. Engr., 447 Riverdale Dr., Glendale 4, Calif.

Malischke, Carl (J'42) (CJMN), Pres., Treas., Charles Malischke Co., 2518 N. 30th St., Milwaukee 10; *for mail,* 6466 Upper Pkwy. N., Wauwatosa 13, Wis.

Mallay, Paul David ('45) (RJMC), Mgr., R.R. Div., Lukens Steel Co., Coatesville, Pa.

Maller, Melvin A. (J'41) (NMBG), Mech. Engr., Watson Labs., Army Air Forces, Red Bank; *for mail,* 70 N. Bath Ave., Long Branch, N.J.

Mallick, Randolph William ('43) (DCMO), Sec. Engr., Hdq. Plant, Layout & Matls. Handling Sec., Westinghouse Elec. Corp.; *for mail,* 325 North Ave., East Pittsburgh, Pa.

Mallon, Charles Joseph ('44) (CEFHOS), Mech. Engr., Design, Dept. of Pub. Works, City of Philadelphia, 223 Chestnut St. Pier, Philadelphia 6; *for mail,* 1224 Harrison St., Philadelphia 24, Pa.

Mallon, David J. (J'46) (SKJL), Steam Power Div., Worthington Pump. & Mchy Corp., Harrison; *for mail,* 171 Sterling Dr., Orange, N.J.

Mallon, Frederick J. (J'36), (ELS), Ch. Engr., Fairmont Creamery Co.; *for mail,* 507 A Ave., Lawton, Okla.

Mallory, Burton Cowles ('23; '34) (SFEKD), Mech. Engr., Stone & Webster Engrg. Corp., 49 Federal St., Boston 7, Mass.

Mallory, Henry Reed ('33) (CT), Exec. V.P., Treas., Cheney Bros.; Pres., Treas., Pioneer Parachute Co.; *for mail,* 68 Prospect St., Manchester, Conn.

Mallory, Walter Franklin ('18; '30) (EFJRSA), Prof. Mech. Engrg., Univ. of Colo.; *for mail,* 915—15th St., Boulder, Colo.

Malloy, John F. ('24; '33) (OHYSNL), Mech. & Struc. Engr., Carbide & Carbon Chemicals Corp., South Charleston; *for mail,* 3714 Staunton Ave., Charleston 4, W.Va.

Mally, George Gregory (J'42) (NBCMJL), Mech. Engr., Bundy Tubing Co., 10951 Hern Ave., Detroit 13; *for mail,* 19316 Teppert St., Detroit 5, Mich.

Malmberg, Philip Otto (J'39) (HBS), Hyd. & Mech. Engr., Tampa Shipbldg. Co., Inc., Tampa; *for mail,* 8109—36th Ave. N., Box 128, Route 2, St. Petersburg 6, Fla.

Malone, James L. (J'44) (CJS), Westinghouse Elec. Corp., Lester Branch P.O., Philadelphia 13, Pa.

Malone, John F. ('37) (CFKS), Asst. Mgr., Dist. Steam Dept., Consltd. Gas, Elec. Light & Power Co. of Baltimore, 503 Lexington Bldg., Baltimore 3, Md.

Maloney, James Dodson, Jr. (J'43) (AFM), Route 14, Lyons Bend Rd., Knoxville, Tenn.

Maloney, Michael Joseph ('21; '35) (CDFKNR), Supt., Poor & Co., Burden Ave., Troy, N.Y.

Malzahn, Gus Edwin (J'45) (BJM), Engr., Charlie's Mch. Works, Inc., Box 66; *for mail,* 1103 N. 6th, Perry, Okla.

Manas, Vincent T. ('44) (FHO), Chief, Mech. & Elec. Engrg. Sec., Fed. Pub. Housing Authority, Longfellow Bldg., Washington 25; *for mail,* 926 Massachusetts Ave., N.W., Washington 1, D.C.

Mandel, Lawrence (J'44) (CJM), Exec. Engr., Masell Mfg. Corp., 195 Front St., Brooklyn, N.Y.

Manderfield, Robert Earl (J'46) (BHM), Project Engr., Fisher Body Div., Gen. Motors Corp., 465 Milwaukee Ave., Detroit; *for mail,* 8717 Morley, Detroit 4, Mich.

Mangan, John R., Jr. (J'42) (AC), Engr., Goodyear Aircraft Corp., Akron; *for mail,* c/o John Ritzman, Box 145, Ellet, Ohio.

Mangan, William Edward (J'42) (CHL), Tech. Asst., Carbide & Carbon Chemicals Corp., South Charleston; *for mail,* 1632 Quarrier St., Charleston 1, W.Va.

Manger, Clarence Philip (J'39), Capt., 604th Bomb Sqd., March Field, Calif.

Manger, Paul A. (J'21) (NBJYHS), Ch. Engr., Buffalo Plant, Farrel-Birmingham Co. Inc., 344 Vulcan St., Buffalo 7; *for mail,* 117 South Dr., Eggertsville 21, N.Y.

Mangler, William Eugene (J'44) (BLN), Mch. & Tool Designer, Bridge Tool & Die Works, 106 S. 16th St., Philadelphia 3; *for mail,* 1201 E. Shelmire Ave., Philadelphia 11, Pa.

Maniates, Peter George (J'41) (ABMCLZ), Bowman Dairy Co., 140 W. Ontario St., Chicago; *for mail,* 4737 W. North Ave., Chicago 39, Ill.

Manierre, George ('17) (D), Propr., Manierre Engrg. & Mchy. Co., 622 Colby Abbot Bldg., Milwaukee, Wis.

Manifold, George O. (J'38) (CMDNOG), Ch. Engr., Universal Lub. Systems, Inc., 743 Allegheny Ave., Oakmont, Pa.

Manilych, Sam (J'43) (MJCD), Mech. Engr., N.Y. Naval Shipyard, Brooklyn 1; *for mail,* 160 Hewes St., Brooklyn 11, N.Y.

Manjoine, Michael Joseph (J'37) (BJNZOA), Research Engr., Westinghouse Research Labs., Ardmore Blvd., East Pittsburgh; *for mail,* 1000 Braddock Rd., Pittsburgh 21, Pa.

Manke, Gustave Leonard (J'41) (ZTMB), Ch. Draftsman, Veeder-Root, Inc., 20 Sargeant St., Hartford 2, Conn.

Mankiewicz, Victor John (J'40) (ANJBG), Stress Analyst, Lockheed Aircraft Corp., Burbank; *for mail,* 1424 S. Mariposa Ave., Los Angeles 6, Calif.

Mankin, Guy ('30) (CFS), 1404—1st Natl. Bank Bldg., Atlanta 3, Ga.

Mankus, Roman Theodore (J'43), Lt. (j.g.), U.S.N.R., Aviation Engr., Specialist, Assembly & Repair Dept., Naval Air Sta., Seattle 5, Wash.; *for mail,* 6030 S. Rockwell, Chicago 29, Ill.

Manley, Humes Baker ('45) (LKZCD), Project Engr., J. F. Pritchard & Co., 2200 Fidelity Bldg., Kansas City 6; *for mail,* 1008 E. 84th Terrace, Kansas City 5, Mo.

Manley, Robert F. (J'37), Field Engr., Bryant Chucking Grinder Co., Springfield, Vt.; *for mail,* 3798 W. 136th St., Cleveland 11, Ohio.

Manley, Robert William (J'42) (CBMYFN), Pvt., 1st Class, Div. of New Devels., U.S.A., Antiaircraft Serv. Test Sec., Army Ground Forces, Board 1, Ft. Bliss, Tex.; *for mail,* 57-22—81st St., Elmhurst, N.Y.

Manley, Sumner M. ('07; '17), Cons. Engr., Procter & Gamble Co., Ivorydale, Cincinnati, Ohio.

Mann, Carl P. ('16; '23), Secy., Treas., A. Kristoferson, Inc., 1300 Rainier Ave., Seattle, Wash.; *for mail,* 403 Main St., Riverton, N.J.

Mann, Frederick L., Jr. (J'45) (ABFK), Test Engr., Ranger Aircraft Engines Div., Fairchild Eng. & Airplane Corp., 712 Fulton St., Farmingdale, L.I., N.Y.

Mann, George Lee (J'42) (BACKSM), Stress Analyst, Douglas Aircraft Co., Inc., 5651 W. Manchester St., Los Angeles; *for mail,* 225-D San Vicente, Santa Monica, Calif.

Mann, Harvey Blaine ('11; '18) (DESZ), Owner, Mann Engrg. Co., 429 Pennsylvania Ave.; *for mail,* 7300 Brighton Rd., Ben Avon, Pittsburgh 2, Pa.

Mann, Isham W., Jr. (J'39) (JLP), 728 State St., New Orleans 15, La.

Mann, John ('30) (HJBY), Ch. Engr., Goulds Pumps, Inc., 240 Fall St., Seneca Falls, N.Y.

Mann, John J. (J'45) (KOS), Designing & Supvg. Engr., Jaros, Baum & Bolles, 415 Lexington Ave., New York; *for mail,* 1421 Mamaroneck Ave., Mamaroneck, N.Y.

Mann, John Winfield (J'36) (ECFKZH), Gen. Oper. Foreman, Socony-Vacuum Oil Co., Inc., 3821 Indianapolis Blvd., East Chicago, Ind.

Mann, Robert M. (J'36) (AOM), Gp. Engr., Glenn L. Martin-Neb. Co., Omaha; *for mail,* 426 Ave. A, Plattsmouth, Neb.

Mannes, Robert Lynn (J'43) (ABHKY), Chief Specialist (X), N. Div., Naval Air Sta., Moffett Field, Calif.

Manney, Charles Joseph ('34; '41) (DJB), Mech. Engr., Columbus-McKinnon Chain Corp., Box 72, Tonawanda, N.Y.

Manning, Edward Vincent (J'39) (AZOJSF), Supvr., Altitude Test Lab., Eclipse-Pioneer Div., Bendix Aviation Corp., Teterboro; *for mail,* 640 Albert Pl., Ridgewood, N.J.

Manning, Ralph Melville (J'42) (ZNC), Factory Engr., West Lynn Works, Gen. Elec. Co., 40 Federal St., West Lynn; *for mail,* 27 Winthrop St., Winchester, Mass.

Manning, Thomas Joseph, Jr. (J'43), Ensign, Naval Air Exper. Sta., Naval Shipyard, Philadelphia, Pa.

Manning, William Thomas ('35) (SBJEKO), Sec. Engr., Indus. Turbine Sec., Westinghouse Elec. Corp., Lester Branch P.O., Philadelphia; *for mail,* 1104 Lindale Ave., Drexel Hill, Pa.

Manny, Erwin Harry (J'39) (CSZEFK), Ch. Serv. Engr., Manning, Maxwell & Moore, Inc., 450 Communipaw Ave., Jersey City 4, N.J.

Mans, Frederick J. ('40) (CL), Major, c/o B.P.M., Willemslaan 2, Batavia-Centrum, N.E.I.

Mansfield, Ernest B. ('36; '44) (YBLR), Sr. Engr., Truck & Bus Tire Devel., Firestone Tire & Rubber Co., Akron; *for mail,* 127 Birdwood Rd., Akron 13, Ohio.

Mansfield, Howard Vaughn ('44) (FRSCK), Ch. Engr., So. Coal Co. Inc., 81 Madison Bldg., Memphis 1; *for mail,* 19 Mosby Rd., Whitehaven, Tenn.

Mansfield, Judson H. ('27) (BMW), Ch. Engr., Greenlee Bros. & Co., 12th St., Rockford, Ill.

Mansfield, William Muir (J'41) (SFKEC), Asst. Ch. Engr., Power Plant, Nev. Mines Div., Kennecott Copper Corp.; *for mail,* Box 1384, McGill, Nev.

Mansky, Clarence Bernard (J'44) (BHNA), Asst. Prof. Mech. Engrg., Cornell Univ., Ithaca, N.Y.

Mantey, Louis Henry (J'41) (NBMZJC), Designer, Research & Devel. Div., Addressograph-Multigraph Corp., 1200 Babbitt Rd., Cleveland 17; *for mail,* 70 Glenwood Ave., Willoughby, Ohio.

Manthei, Edward Charles (J'38) (OKS), Mech. Engr., Univ. of Ill., Urbana; *for mail,* 605 S. Edwin St., Champaign, Ill.

Manuel, Harold Eugene (J'38) (MLDN), Mech. Engr., Buick, Oldsmobile, Pontiac Assembly Div., Gen. Motors Corp., Fairfax & Kindleberger Sts., Kansas City, Kan.; *for mail,* 2834 Askew, Kansas City 3, Mo.

Manuele, Joseph, Jr. (A'42) (CDLMOY), Dir., Quality Control, Westinghouse Elec. Corp., East Pittsburgh; *for mail,* Box 169, R.D. 4, Irwin, Pa.

Manz, Louis C. ('13) (ABFM), Inspr., Engrg. Matl., Philadelphia Ord. Dist., Philadelphia; *for mail,* 3322 Friendship St., Philadelphia 24, Pa.

Mao, Easin ('46), Supt. of Shops, Chinese Natl. Rys. Ministry of Communications, Chungking, China; *for mail,* c/o Chinese Supply Comm., 2224 R St., N.W., Washington 8, D.C.

Mapes, Joe Milton (J'39) (ACM), 311 Delaware St., Corry, Pa.

Marantette, Louis Edward (J'43) (ALM), U.S. Navy; Box 324, Columbia Falls, Mont.

Marazzini, Gilbert John (J'44) (DCL), Lt. (j.g.), U.S.N.R., Navy 926, F.P.O., San Francisco, Calif.; *for mail,* 500 W. 114th St., New York 25, N.Y.

Marcero, Aloysius ('23) (BFS), Plant Engr., Detroit Edison Co., 2000—2nd Ave., Detroit, Mich.

March, John Parrish (J'42), 1st Lt., Army Air Forces, Air Trans. Comd.; 7302 River Rd., Cincinnati 33, Ohio.

March, Perrin George, III (J'39) (CMN), Pres., Cincinnati Shaper Co., Hopple, Elam & Garrard Sts., Cincinnati 25; *for mail,* 7302 River Rd., Cincinnati 33, Ohio.

Marchant, John Henry ('36) (EAKBF), U.S. N.R., Bunker Hill Rd., Andover, Conn.

Marchant, Richard Douglas ('36; '45) (CBJ MND), Designing Engr., Capacitors, Gen. Elec. Co., 100 Woodlawn Ave.; *for mail,* 40 Buel St., Pittsfield, Mass.

Marco, Salvatore Michael (J'38) (NBKJZ), Assoc. Prof. Mech. Engrg., Ohio State Univ., Columbus 10, Ohio.

Marcotte, Robert Lee (J'43) (NMZD), Lt. (j.g.), U.S.N.R., Gunnery, Watch & Div. Officer, U.S.S. *Cortland,* APA-75, F.P.O., San Francisco, Calif.; *for mail,* 5100 E St., Lincoln 2, Neb.

Marder, Ira K. (J'40) (CMYJAD), Prod. Dept., Astor, Ramel Mfg. Co., 249 Brook Ave., Bronx; *for mail,* 245 Amherst St., Brooklyn 29, N.Y.

Marek, Clarence Thomas (J'43) (JKYM), Instr. in Engrg. Shop Practice, Purdue Univ.; *for mail,* 209 De Hart, West Lafayette, Ind.

Margrave, Wilton (J'37) (ACEMHN), Mech. Engr., Parker Appliance Co., 17325 Euclid Ave.; *for mail,* 3028 E. 132nd St., Cleveland 20, Ohio.

Marich, Frederick ('37; '45) (AJMNOR), Design Engr., Farrand Optical Co., 4401 Bronx Blvd., New York; *for mail,* 55 W. 55th St., New York 19, N.Y.

Marin, Joseph ('36) (BAOYJ), Prof. Engrg. Mechanics, Pa. State College, State College, Pa.

Marinelli, Gino J. (J'37) (SFLEHB), *Student Award,* '37; Engrg. Dept., Anaconda Copper Min. Co., 25 Broadway, New York 4, N.Y.; *for mail,* 25—2nd St., Dumont, N.J.

Marinoff, George (J'44) (GYJM), Instr., Dept. of Engrg. Drawing, Case Sch. of Applied Sci., 10900 Euclid Ave., Cleveland, Ohio.

Marion, Frank Ivichievich ('26; '34) (CESF), Lt., Fuel & Lub. Engr., Indus. Dept., U.S.N., Box 6093, Sta. A; *for mail,* 2601 Octavia St., New Orleans 15, La.

Mark, Clayton, III (J'38), Engr., Clayton Mark & Co., 1900 Dempster St., Evanston; *for mail,* Sheridan Rd., Wilmette, Ill.

Mark, Melvin (J'45) (NKBAJH), Instr. in Mch. Design, Inst. of Tech., Univ. of Minn., Minneapolis 14; *for mail,* 1484 Summit Ave., St. Paul 5, Minn.

Mark, Walter J. ('26) (DGWLSB), Mech. Engr., Natl. Housing Agency, Fed. Pub. Housing Authority, Washington, D.C.; *for mail,* 317 S. Exchange St., St. Paul 2, Minn.

Markell, John, Jr. (J'41) (AKOE), Devel. Engr., Aviation Gas Turbine Div., Westinghouse Elec. Corp., Lester; *for mail,* 714 Colwell Rd., Grace Park, Chester, Pa.

Marker, Roland Howard ('21; '38) (OSEFD), Partner, Froehlich & Emery Engrg. Co., 410 Toledo Trust Bldg., Toledo 4, Ohio.

Mengel, John Franklin (J'44), 1560 Linden St., Bethlehem, Pa.
Mengel, Walter Alvin (J'43) (MCJDNO), Mfg. Engr., Sperry Gyroscope Co., Inc.; *for mail,* 18 Clover Dr., Great Neck, L.I., N.Y.
Mengers, Charles F. (J'42) (AEFS), 137 Kendall Blvd., Oaklyn, N.J.
Menke, John Roger (J'45) (BCJ), Cons. Engr., 210 W. 70th St., New York 23, N.Y.
Menkes, Sherwood Bradford, III (J'42) (MJCBDA), Prod. Engr., Dept. 9764, West. Elec. Co., Inc., 300 Central Ave., Kearny, N.J.; *for mail,* 290 Riverside Dr., New York 25, N.Y.
Menner, Frederic ('19) (DO), Engrg. Sales Rep., 915 Olive St., St. Louis 1, Mo.
Menon, V. K. A. ('23; '33; '35), Cochin Govt., Trichur, Cochin State, India.
Menshon, William R. ('28; '35) (CLS), Barrett Div., Allied Chem. & Dye Corp., 40 Rector St., New York, N.Y.
Menson, John Lewis (J'37) (FKRS), Engr., Superheater Co., East Chicago, Ind.
Mensonides, Sjoerd ('22) (SE), V.P., Charge Oil Fields Div., Farrar & Trefts, Inc., 20 Milburn St., Buffalo 12, N.Y.
Mentzer, Ralph Bender (J'37) (CJMNZ), Mch. Exper. Supvr., Hamilton Watch Co., Lancaster, Pa.
Menz, Charles Newman (J'38) (LMCN), Plant Engr., Marshall Eclipse Div., Bendix Aviation Corp.; *for mail,* 190 Hoosick St., Troy, N.Y.
Menzl, Leon ('21; '24) (DKOS), Cons. Engr., 129 Front St., New York 5, N.Y.
Mercer, Aaron Loveridge, Jr. (J'42) (COMRDE), 2472 Overlook Rd., Cleveland Heights, Ohio.
Mercer, Charles Franklin ('37) (KS), Head., Dept. of Physics, Univ. of S.C., Columbia 19; *for mail,* 219 S. Waccamaw St., Columbia 48, S.C.
Mercer, George Anderson, Jr. ('23; '31) (C), Pres., Steel Products Co., Inc., Box 1007, Savannah, Ga.
Merchant, Mylon Eugene ('45) (JBM), Research Physicist, Research Dept., Cincinnati Milling Mch. Co., Cincinnati 9, Ohio.
Mercier, Harvey O. ('30) (LFK), Natl. Biscuit Co., 449 W. 14th St., New York 11, N.Y.
Mercier, Joffre Pershing (J'41) (JOCK), Asst. Supt., Dixie Mch. Welding & Metal Works, 1031 Annunciation St., New Orleans 13, La.
Mercier, Stanley M. ('36) (DCBJHG), Ch. Engr., Jeffrey Mfg. Co., Columbus 16; *for mail,* 2565 Bexley Park Rd., Columbus 9, Ohio.
Meredith, Diven (J'36) (KMCS), Gen. Delivery, Lockeford, Calif.
Meredith, Henry H., Jr. (J'39) (JLM), Dist. Petroleum Engr., Humble Oil & Refining Co., Encino, Tex.
Meredith, Wynn ('13) (BCE), Res. Partner, Sanderson & Porter, 1 Montgomery St., San Francisco, Calif.
Meriam, James Lathrop (J'42) (BNMZGJ), Asst. Prof. Mech. Engrg., Dept. of Engrg., Univ. of Calif., Berkeley 4, Calif.
Merkin, Eugene (J'45), Stress Analyst, Republic Aviation Corp., 42 Broadway, New York; *for mail,* 3360 Bronx Blvd., New York 67, N.Y.
Merkle, Richard William ('24; '40) (CDJM), Asst. Prod. Mgr., West. Cartridge Co., East Alton; *for mail,* 112 Springer Ave., Edwardsville, Ill.
Merl, Milton Francis ('28; '34; '36) (FLSZ), Sales & Serv. Engr., Republic Flow Meters Co., 213 Red Rock Bldg., Atlanta 3, Ga.
Merrell, Frank Laird (J'36) (CMWYFR), Sgt. Maj., Adj. Gen. Dept., Hdq. & Hdq. Det., 560th QM. Gp., A.P.O. 887, New York, N.Y.; *for mail,* 3401 Fremont Ave. S., Minneapolis 8, Minn.
Merrell, Spencer Atkins ('44), V.P., Mgr., Waterways Transport, Inc., 16-D Railway Exchange Bldg., St. Louis, Mo.
Merriam, Carroll Fuller ('16; '21; '24) (H), Spec. Studies, Pa. Water & Power Co., Baltimore 3, Md.
Merriam, Henry Parker ('87; '96), Retired; Hubbardston, Mass.
Merriam, Kenneth Gerald ('23; '30; '35) (ZBAHN), Prof., Aeromechanics, Worcester Poly. Inst.; *for mail,* 56 Havelock Rd., Worcester, Mass.
Merrick, Charles M., III ('26; '36) (CMADJL), Indus. Engr., Mgmt. Engrg. Dept., Glenn L. Martin Co., Baltimore 3; *for mail,* 609 Allegheny Ave., Towson 4, Md.
Merrill, Bennett Wallace (J'44) (NMJCAD), Spec. Engr., Maint., Carnegie-Ill. Steel Corp., 3426 E. 89th St., Chicago 17; *for mail,* 8216 Harper Ave., Chicago 19, Ill.
Merrill, Carle J. ('16), Treas., Mgr., C. J. Merrill, Inc., 54 St. John St., Portland, Me.
Merrill, David R. ('35) (LEY), Devel. Dept., Rohm & Haas Co., Inc., Box 219, Bristol, Pa.
Merrill, Donald G. (J'19) (FKL), Devel. Engr., Hartford-Empire Co., P.O. Drawer 1620, Hartford 1; *for mail,* 534 Fern St., West Hartford 7, Conn.
Merrill, Geo. H. ('98; '17), Pres., Merrill Bros., 56-02 Arnold Ave., Maspeth, L.I., N.Y.
Merrill, Robert Dodge (J'45), Engr., Naval Research Lab., Anacostia Sta., Washington; *for mail,* Apt. 3, 10 Danbury St., S.W., Washington 20, D.C.
Merrill, S. Clifford ('18; '23; '30) (CBAM), Asst. Gen. Mgr., Automotive Div., Timken Roller Bearing Co., Inc., 8500 Woodward Ave., Detroit 2, Mich.
Merritt, George Irvin (J'43), 359—3rd St., Newburgh, N.Y.
Merritt, Harold W. (J'21) (BHKZ), Assoc. Prof. Physics, Cooper Union Sch. of Engrg., Cooper Sq., New York 3, N.Y.
Merritt, Jos. ('07) Pres., Treas., Mech. Engr., Hartford Spec. Mchy. Co., 287 Homestead Ave., Hartford, Conn.
Merritt, Richard Todd, Jr. (J'46) (JLZ), Tech. Asst., Carbide & Carbon Chemicals Corp., South Charleston 3; *for mail,* 28 Ruffner Ave., Charleston 1, W.Va.
Mershon, Clarence Earl (J'44) (ABJ), Ch. Draftsman, Aluminum Co. of Am.; *for mail,* 100 Ash Ave., Troutdale, Ore.
Mershon, Ralph Davenport ('00) (BAYE), 2000 Tiger Tail Ave., Miami 33, Fla.
Mervine, William G. ('43) (SECHO), Box 127, Phoenixville, Pa.
Merwin, Harry H. ('19; '35) (NBDMH), Mch. Designer, West. Elec. Co., Inc., 100 Central Ave., Kearny; *for mail,* 254 Springfield Ave., Rutherford, N.J.
Meseroll, Vincent Francis (J'38) (JCLD), 33 N. 6th Ave., Highland Park, N.J.
Mesiboff, Milton Joseph (J'38) (SKNMBJ), Mar. Engr., N.Y. Naval Shipyard, Brooklyn; *for mail,* 628 Montgomery St., Brooklyn 25, N.Y.
Mesick, Benjamin Schultz ('39) (JLCBDM), Sub-Office Chief, Research & Devel. Serv., Calif. Inst. of Tech., Pasadena 4; *for mail,* 454 W. 7th St., Claremont, Calif.
Mesinger, Frederick W. ('24; '29), V.P., Norma-Hoffmann Bearings Corp., Stamford; *for mail,* Glenbrook, Conn.
Messaros, Frank Charles ('40) (SCFN), Sales Mgr., Mar. Div., Am. Engrg. Co., Aramingo & Cumberland Sts., Philadelphia 25; *for mail,* 1128 E. Price St., Philadelphia 38, Pa.
Messenger, Joseph Alden ('38) (KLS), V.P., Buell Engrg. Co., Inc., 70 Pine St., New York 5, N.Y.
Messenger, Paul B. (J'41) (ABM), Cardington, Ohio.
Messenger, Robert P. ('13; '31) (NMOC), V.P., Internatl. Harvester Co., 180 N. Michigan Ave., Chicago 1, Ill.
Messer, Eugene W. (J'41) (SEBAJ), c/o T. J. Laird, R.D. 1, Muncy, Pa.
Messer, John Dickinson (J'43) (KBE), Mech. Engr., Engrg. Dept., Weyerhaeuser Timber Co., Tacoma Bldg.; *for mail,* 5 California, Lincoln Heights, Tacoma, Wash.
Messer, Rowland E. (J'36) (WSCMHK), Assoc. Mar. Engr., Puget Sound Naval Shipyard; *for mail,* Box 2512, Route 4, Bremerton, Wash.
Messersmith, Charles William ('33; '37) (SEZKF), Prof., Exper. Mech. Engrg., Purdue Univ., West Lafayette, Ind.
Messersmith, Eldon Maurice ('37; '45) (DCMOE), Asst. to Sales Mgr., Robison Mchy. Co., 245 W. South Temple St., Salt Lake City; *for mail,* 868 N. 2nd W., Lehi, Utah.
Messick, William Wallace (J'43) (HKS), Lt., U.S.N.R., 816 S. Lake Ave., Pasadena, Calif.
Messinger, Joe Prout (J'21) (ACEF), Sales Engr., Stand. Oil Co. of N.J., 26 Broadway, New York 4, N.Y.
Messner, Manfred ('13; '17; '31) (OKFHCA), Ch. Engr., Treas., Bing & Bing, Inc., 119 W. 40th St., New York 18; *for mail,* 2 N. Clover Dr., Great Neck, L.I., N.Y.

Mitchell, Fred Tom, Jr. (J'43) (CMDL), 50 Peterboro, Detroit 1, Mich.
Mitchell, Harold Clifton (J'38) (BSKLYR), Mech. Dept., Tide Water Associated Oil Co., E. 22nd St., Bayonne, N.J.; *for mail,* 71 Orange St., Brooklyn 2, N.Y.
Mitchell, Harry ('43) (CMTBD), Gen. Supt., Whitin Mch. Works, Main St.; *for mail,* 379 Hill St., Whitinsville, Mass.
Mitchell, Henry M. (J'39), 2020 Campbell Ave., Schenectady, N.Y.
Mitchell, James Ronaldson, Jr. (J'45) (BOY), Welding Engr., Farrel-Birmingham Co., Inc.; *for mail,* 243 Wakelee Ave., Ansonia, Conn.
Mitchell, Jean F. (J'35), Sales & Devel. Engr., Chamberlain Corp., Waterloo, Iowa.
Mitchell, John Earl, Jr. (J'38) (MJCDES), Mgr., Planning & Estimating, Engrg. Dept., Lukenweld, Inc., Coatesville, Pa.
Mitchell, John Gordon ('44) (TYKLBN), Research Engr., Celanese Corp. of Am.; *for mail,* 801 Braddock Rd., Cumberland, Md.
Mitchell, Lester Felter ('45) (BCHJ), Mgr., Engrg., Addressograph-Multigraph Corp., 1200 Babbitt Rd., Cleveland 17; *for mail,* 2673 Wrenford Rd., Shaker Heights 22, Ohio.
Mitchell, Nathaniel McDonald ('37) (CMOTZ), Pres., Mgr., Barnes Textile Associates, Inc., 10 High St., Boston 10, Mass.
Mitchell, Norman Tuley ('27; '35) (SAECFK), Supvr., Power Engr., Cadillac Motor Car Div., Gen. Motors Corp., Clark St., Detroit 32; *for mail,* 9125 Birwood, Detroit 4, Mich.
Mitchell, Orville ('44) (BKM), V.P., Ch. Engr., John E. Mitchell Co., 3800 Commerce St.; *for mail,* 8441 San Fernando Way, Dallas, Tex.
Mitchell, Robert Barringer (J'40) (HJNCGZ), Westco Works, Fairbanks, Morse & Co., 4301 S. Spring Ave.; *for mail,* 2404 Bristow Ave., St. Louis 16, Mo.
Mitchell, Robert Franklin (J'41) (WMJNYB), Capt., Trans. Corps, Contract Termination Officer, Procurement Div., Office of Chief of Trans., New Orleans Port of Embarkation, New Orleans; *for mail,* 33 Papworth St., New Orleans 20, La.
Mitchell, Stephen George (J'45) (EKH), Asst. Engr., West. Elec. Co., Inc., New York, N.Y.; *for mail,* Box 453, University, Ala.
Mitchell, W. G. (J'41), Ch. Engr., Independent Pneumatic Tool Co., State & Claim Sts.; *for mail,* 3 S. View St., Aurora, Ill.
Mitchell, William F. (J'36) (CFLSRZ), Supt., Pa. Salt Mfg. Co., 4655 Biddle Ave., Wyandotte, Mich.
Mitchell, William Henry ('13; '35) (HJR), Mech. Engr., Niagara Falls Power Co., Elec. Bldg., Buffalo 3; *for mail,* 532—12th St., Niagara Falls, N.Y.
Mitchell, William Howard (J'41) (NKHJB), Mech. Design Engr., Westinghouse Elec. Corp., Lima, Ohio.
Mitchell, William John (J'41) (NOJHMG), Welding Engr., Stress Analyst, E. W. Bliss Co., 53rd St. & 1st Ave., Brooklyn; *for mail,* 1212 Ocean Ave., Brooklyn 30, N.Y.
Mitchell, William Montgomery ('42) (ABHMN), Stress Analyst, Consltd. Vultee Aircraft Corp., Vultee Field, Downey; *for mail,* 1147—6th St., Santa Monica, Calif.
Mitchell, William Sibley (J'44) (CJMDN), 1220 S. Center St., Terre Haute, Ind.
Mitelman, Leon V. ('42) (EFHKOS), Mech. Engr., Neiler, Rich & Bladen, 431 S. Dearborn St., Chicago 5; *for mail,* 1140 Pratt Blvd., Chicago 26, Ill.
Mitsch, Edward Henry ('21; '26; '35) (CFS), Results Engr., Elec. Generation, Cincinnati Gas & Elec. Co., Cincinnati 2; *for mail,* 1007 Omar Pl., Cincinnati 8, Ohio.
Mitsui, Koei (J'45) (HMY), 234—1st Ave., Toronto 8, Ont., Can.
Mittelberger, Frank (J'40) (BONCGA), Cons. Engr., 88-11 Elmhurst Ave., Elmhurst, L.I., N.Y.
Mittendorf, William ('16) (FS), Fuel Engr., Holmes-Darst Coal Corp., Trans. Bldg., Cincinnati 2; *for mail,* 6269 Grand Vista Ave., Cincinnati, Ohio.
Mittleman, Joel Jerry (J'46), West. Mchy. Co., 50 Church St., New York; *for mail,* 7814—15th Ave., Brooklyn 28, N.Y.
Mittman, Carl Friedrich ('45) (LO), Consultant, Engr., Buflovak Equip. Div., Blaw-Knox Co., 1543 Fillmore Ave., Buffalo 11; *for mail,* 323 Westgate Rd., Kenmore, Buffalo 17, N.Y.
Mitzelfeld, Marvin Walter (J'44) (BEHJNS), Mech. Engr., Mch. Designer, Natl. Twist Drill & Tool Co., Rochester, Mich.
Mixter, George Webber ('99; '08), V.P., Day & Zimmermann, Inc., 165 Broadway, New York 6, N.Y.
Mjolsnes, Elliot Leffler (J'35) (BMZ), Checker, Designer, Vinco Corp., Schaefer Highway & Joy Rd., Detroit; *for mail,* 19465 Glastonbury Rd., Detroit 19, Mich.
Mlynko, Walter Francis (J'44), Pat. Atty. Trainee, Bosworth & Sessions, 1337 Guardian Bldg., Cleveland; *for mail,* 14508 Strathmore Rd., East Cleveland 12, Ohio.
Moats, William L. (J'40), Ensign, U.S.N.R., U.S.S. *Downes,* DD-375, F.P.O., New York, N.Y.
Moberg, Eric Skoglund (J'39) (SEKBA), Test Mar. Engr., Naval Shipyard, Boston; *for mail,* 153 Waverly St., Arlington 74, Mass.
Mochel, Myron George ('30; '36) (CNJBSM), Supvr. Trng., Moore Steam Turbine Div., Worthington Pump & Mchy. Corp., Wellsville, N.Y.
Mock, Loyal Kay (J'37) (MOYH), Sr. Surveyor, Shell Oil Co., Inc., Box 744; *for mail,* 907 Stone, Great Bend, Kan.
Mockridge, Chester R. ('22; '39) (HLBJNS), Centrifugal Pump Engr., Worthington Pump & Mchy. Corp., Harrison; *for mail,* 24 Coeyman Ave., Nutley 10, N.J.
Modes, Edward E. (J'37) (ZBKH), Devel. Engr., Powers Regulator Co., 2720 Greenview Ave., Chicago 14; *for mail,* 2316 Granville Ave., Chicago 45, Ill.
Moe, Clarence M. ('42) (CHS), Sr. Civ. Engr., Charge of Recreational Devel. of Lake Areas, U.S. Engr. Office, 300 Broadway, Little Rock, Ark.
Moeller, Harry A. ('42) (RCMJB), Asst. Ch. Mech. Engr., Buckeye Steel Castings Co., 2211 Parsons Ave., Columbus 7, Ohio.
Moeller, Henry George ('44), Gen. Partner, Gen. Mgr., Sioux Alfalfa Meal Co., Vermillion, S.D.
Moeller, Robert (J'37) (NBJHYK), Mech. Engr., Engrg. & Design Sec., David Taylor Model Basin, Washington, D.C.; *for mail,* 9 Froude Circle, Bethesda 14, Md.
Moeller, William ('17) (CJM), Ch. Engr., Lone Star Cement Corp., 1217—1st Natl. Bank Bldg., Dallas 1, Tex.
Moen, Leclanché ('17), Engrg. and Investment Banking, Rm. 429, 522—5th Ave., New York 18, N.Y.
Moen, Levi W. ('40), 123 Lynwood Ave., Syracuse, N.Y.
Moen, Richard H. (J'44) (JCMNYO), Partner, Schmid Bros., 317 Filbert St., Lancaster; *for mail,* Millway Farm, Millersville, Pa.
Moen, Walter B. (J'40) (SKB), Instr. in Mech. Engrg., Pratt Inst., Brooklyn 5; *for mail,* 70 Lincoln Ave., Rockville Centre, N.Y.
Moerk, John Carroll ('43) (NBDM), Div. Engr., Fairbanks, Morse & Co.; *for mail,* 614 W. Stephenson St., Freeport, Ill.
Moesinger, Fred, Jr. (J'41) (CJK), c/o Cudworth, 753 Lyons Ave., Irvington, N.J.
Moffat, George Nichol ('24; '35) (JNYBW), Prof. Engrg. Matls., Ohio State Univ., Columbus 10, Ohio.
Moffatt, Charles Richardson (J'42) (COJKYZ), Asst. Divisional Engr., Calco Chem. Div., Am. Cyanamid Co., Bound Brook, N.J.
Moffett, Henry C. ('21) (CEJOSY), Ch. Engr., Moffett & Troop, Inc., 4 Smithfield St., Pittsburgh 22; *for mail,* Box 152, R.D. 1, Library, Pa.
Moffett, John Theodore ('45) (BEKORS), Turbine Application Engr., Gen. Elec. Co., 1405 Locust St., Philadelphia 2, Pa.
Moffitt, Robert Colborn ('25; '32) (CNE), Pres., Thunderbird Mines Ltd., N.P.L., Box 743, Seattle 11, Wash.
Moglia, Guido Albert (J'43) (JBHYAC), Pvt., Army Air Forces, Sqd. A-4, A.P.O. 19909-A, c/o Postmaster, New York; *for mail,* 84-38 Daniels St., Jamaica 2, N.Y.
Mohler, Lee Jason (J'38) (AESRC), Elec. Engr., Gen. Elec. Co., 1 River Rd., Schenectady, N.Y.
Mohler, Robert Claude ('31; '35), M.M., O'Okiep Copper Co., Ltd., O'Okiep; *for mail,* Nababeep, Namaqualand, South Africa.
Mohler, Valentine Joseph ('41) (BCLMOZ), Ch. Loan Engr., Reconstruction Finance Corp., 208 S. La Salle St., Chicago; *for mail,* 563 Ashland Ave., River Forest, Ill.
Mohn, Henry LeRoy ('43) (CKBFNO), Ch. Engr., Fitzgibbons Boiler Co., Inc., Oswego, N.Y.
Mohn, Paul Eugene ('28; '34) (SEFKAH), Prof. Mech. Engrg., Head, Engrg. Dept., Univ. of Buffalo, Buffalo 14, N.Y.
Moir, Harry L. ('42) (FEAM), Tech. Adviser, Marketing Dept., Pure Oil Co., 35 E. Wacker Dr., Chicago 1, Ill.
Molé, Harvey E. ('01; F'41), Box 205, Summit, N.J.
Moler, Frank White, Jr. ('34; '45) (KMS), Mech. Engr., Supvr., Design, Griscom-Russell Co., 285 Madison Ave., New York 17, N.Y.
Molinari, Wilfred Henry ('35; '44) (BCJLMN), Engr., Chambers Works, E. I. du Pont de Nemours & Co.; *for mail,* Golfview Pk., Penns Grove, N.J.
Moline, Adolph Alexander ('31; '35) (CBHJN), Ch. Engr., Canadian Westinghouse Co., Ltd., 286 Sanford Ave. N., Hamilton, Ont., Can.
Molitor, Arvid Axel (J'44) (NMBC), Prod. Engr., Process Dept., Zenith Radio Corp., 6001 W. Dickens Ave., Chicago; *for mail,* 228 Hamilton Ave., Elgin, Ill.
Moll, Harvey Donald (J'45) (S), 108 E. 3rd, Lansdale, Pa.
Moller, Carl G. (J'46) (CEF), 455 W. 23rd St., New York, N.Y.
Moller, H. Frederick ('23; '25; '35) (CM), Mgr., Valve Div., Reed Roller Bit Co., Box 2119; *for mail,* 2812 Wheeler, Houston 1, Tex.
Moller, Jos. A. ('24; '30; '34) (AEF), Pure Oil Co., 35 E. Wacker Dr., Chicago 1, Ill.
Molleson, Gilbert Cox ('27) (SBHND), Chief, Bldg. & Mech. Sec., Engrg. Div., Corps of Engrs., U.S.A., Office of Div. Engr., S. Atlantic Div., 50 Whitehall St., Atlanta 3; *for mail,* 1426 Boulevard, N.E., Atlanta, Ga.
Molokie, Stephen W. ('17; '25; '35) (HLS), 1622 Edison Dr., San Antonio, Tex.
Molony, Noblett Joseph ('27) (CDLA), Mech. Engr., Natl. Biscuit Co., 449 W. 14th St., New York 11; *for mail,* 4 E. 95th St., New York 28, N.Y.
Molter, Frank H. (A'22), 27 Harding Ave., West Hempstead, L.I., N.Y.
Molvie, William A. (J'41) (OSKFZ), Dravo Corp., Dravo Bldg., 300 Pennsylvania Ave., Pittsburgh; *for mail,* 1135 Hillsdale Ave., Pittsburgh 16, Pa.
Momot, William Eovich (J'43) (CJMN), Owner, Gen. Mgr., Momot Metal Products Co., 42-45—27th St., Long Island City 1; *for mail,* 1738—53rd St., Brooklyn 1, N.Y.
Monaco, Anthony Philip (J'38) (ABCNMK), Ch. Engr., Bunyard Aircraft Co., 37-26—32nd St., Long Island City 1; *for mail,* 4127—76th St., Jackson Heights, N.Y.
Monaco, John Charles ('45) (CJKL), Engr., Patterson-Kelley Co. Inc., East Stroudsburg; *for mail,* R.D. 1, Stroudsburg, Pa.
Moncrief, Ernest (J'37) (LEFYZK), Asst. Dir. of Process, Fluor Corp. Ltd., Box 2889, Grand Ave. Sta., Kansas City, Mo.
Mongello, Thomas (J'43) (ANM), 101-21—102nd St., Ozone Park, N.Y.
Monich, Michael Theodore (J'41) (BJG), Project Engr., New Departure Div., Gen. Motors Corp., Bristol; *for mail,* 97 Circle St., Forestville, Conn.
Monks, George S., Jr. (J'39), 205—41st St., Manhattan Beach, Calif.
Monnier, Rene A. ('45) (BC), Mech. Engr., R. Hoe & Co., Inc., 910 E. 138th St., New York, N.Y.; *for mail,* 1 W. Harriet Ave., Palisades Park, N.J.
Monro, Donald A. ('45) (CPS), Acting Ch. Engr., Stand. Oil Co. of Ind., 910 S. Michigan Ave., Chicago, Ill.

Myers, Jas. (A'26), Secy., Indus. Div., Fed. Council of Churches of Christ in Am., 297—4th Ave., New York, N.Y.

Myers, John Beasley (J'41) (A), Engr., Glenn L. Martin Co., Baltimore 3; *for mail*, Odenton, Md.

Myers, Maurice Earl ('45) (OCWND), Cons. Engr., 1205 Am. Bank Bldg., Portland; *for mail*, 5305 N. Kerby, Portland 7, Ore.

Myers, Oscar Bruce, Jr. (J'45) (HAOMC), Design Engr., with Dalmo Victor, San Carlos; *for mail*, 915 S. Fremont, San Mateo, Calif.

Myers, Phillip Samuel (J'42) (EFACKB), Instr., Mech. Engrg. Dept., Univ. of Wis., 1518 University Ave., Madison 5, Wis.

Myers, Robert Duane ('21; '29) (AFS), Lt. (j.g.), CEC-V(S), U.S.N.R., 67th Naval Constr. Bn., F.P.O., San Francisco, Calif.

Myers, Robert Thomas ('44) (NMCJLK), Ch. Engr., Sprague-Sells Div., Food Mchy. Corp.; *for mail*, 714 S. 4th St., Hoopeston, Ill.

Myers, Thomas Gary ('32) (NBCHYD), V.P., Ch. Engr., U.S. Elec. Motors, Inc., 200 E. Slauson Ave., Los Angeles 54, Calif.

Myers, William Joseph (J'45) (SKENZF), Graduate Mech. Engrg. Student, Graduate House, Mass. Inst. of Tech., Cambridge 39, Mass.

Myers, William Kurtz ('21) (CJR), Pres., Penn Steel Castings Co., Front & Penn Sts., Chester, Pa.

Myhre, Emmett Bernard (J'36) (SHF), Engr., U.S. Bur. of Reclamation; *for mail*, 1216—5th, Boulder City, Nev.

Mylroie, John Ellis ('36; '45) (AC), Field Serv. Engr., Boeing Aircraft Co., Seattle 8; *for mail*, Box 70, Route 2, Renton, Wash.

Mylting, Lauritz Emil ('37) (HMCDN), Ch. Engr., Allen-Sherman-Hoff Co., 225 S. 15th St., Philadelphia, Pa.

Mynderse, Chauncey Nicklin ('25) (BCMZ), V.P., Fulton Sylphon Co., Kingston Pike, Knoxville 4; *for mail*, Box 263, 2008 Terrace Ave., Knoxville 16, Tenn.

N

Nabow, David ('41) (BHS), Ch. Designing Engr., Duke Power Co., 420 S. Church St., Charlotte 1, N.C.

Nace, John Foley (J'41) (SEO), Application Engr., Fed. & Mar. Div., Gen. Elec. Co., Schenectady; *for mail*, 1737 East. Pkwy., Schenectady 8, N.Y.

Nachman, Harry Simon (J'44) (CJK), Propr., H. S. Nachman & Associates, 179 W. Washington St., Chicago 2, Ill.

Nachman, Henry L. ('21) (SKB), Prof. Thermodynamics, Ill. Inst. of Tech., 3300 Federal St., Chicago 16, Ill.

Nacy, Robert James (J'45) (BDJKMS), Plant Engrg. Draftsman, Murray Corp. of Am., 7700 Russell, Detroit 21, Mich.

Nadai, A. L. ('29) (ABJKSY), Cons. Mech. Engr., Westinghouse Research Labs., East Pittsburgh, Pa.

Nadeau, Robert Frederick (J'39) (CMTY), Prod. Engr., Tubbs Cordage Co., 22nd & Iowa Sts., San Francisco 7, Calif.

Nadler, Robert A. (J'42) (NMCDJL), V.P., Charge of Engrg. & Sales, Nadler Fdy. & Mch. Co., Inc., Plaquemine, La.

Naeseth, Rodger Leonard (J'41) (A), Capt., Aero. Research, Langley Memorial Aero. Lab., Natl. Advis. Com. for Aero., Langley Field; *for mail*, 209 Algonquin Rd., Hampton, Va.

Nagai, Gladyes Masao (J'41) (ABM), Draftsman, Houston Fdy. & Mch. Co., 2005 White St., Houston; *for mail*, Box 26, Almeda, Tex.

Nagel, Eric W. ('38) (CDK), Factory Mgr., Wrought Iron Range Co., 5661 Natural Bridge Ave., St. Louis 20, Mo.

Nagel, Theo. ('18) (FKS), Cons. Engr., 76 Remsen St., Brooklyn, N.Y.

Nagle, March Emmett ('42) (BCE), Plant Mgr., Kimble Glass Co., 12th & Arnold Sts., Chicago Heights, Ill.

Nagle, Perry Ira ('44) (BHL), Mgr., Indus. Pumps, Am. Manganese Steel Div., Am. Brake Shoe Co.; *for mail*, 258 W. 16th Pl., Chicago Heights, Ill.

Nagler, Forrest ('18) (AHSK), *Life Member for Distinguished Service*, '21; Ch. Mech. Engr., Allis-Chalmers Mfg. Co., Box 512, Milwaukee 1, Wis.

Nagler, Larry H. ('45) (MCFYB), Tech. Editor, *Motor Magazine*, 572 Madison Ave., New York 22, N.Y.; *for mail*, 16628 Pinehurst, Detroit 21, Mich.

Naiman, Robert (J'42) (JMNYZ), Electronics Technician's Mate, 2nd Class, U.S.N.R., U.S.S. *Portsmouth*, CL-102; *for mail*, 8 Haley St., Roxbury 19, Mass.

Nairne, Clayton Ludlow ('43) (CKSFAY), Asst. to Exec. V.P., New Orleans Pub. Serv., Inc., 317 Baronne St., New Orleans 12, La.

Nalbandian, Haig Sarkis (J'44) (AHBS), Asst. Engr., Cent. Tech. Dept., Shipbldg. Div., Bethlehem Steel Co., 97 E. Howard St., Quincy 69; *for mail*, 86 S. Crescent Circuit, Brighton 35, Mass.

Näll, Robert Lauren ('43) (LDM), Plant Engr., Flintkote Co., 4500 N. Galvez St., New Orleans 4; *for mail*, 1139 State St., New Orleans 18, La.

Nalven, Robert M. (J'40) (KSHL), Mech. Engr., Combustion Engrg. Co., Inc., 200 Madison Ave., New York 16; *for mail*, 8267 Austin St., Kew Gardens, N.Y.

Nankivell, John Elbert (J'43) (EHS), 201 Hackensack St., East Rutherford, N.J.

Nantz, Merle Edward ('43) (HBNJYL), Hydroelec. Engr., Charge Hydroelec. Design, U.S. Engr. Office, 1709 Jackson St.; *for mail*, Box 869, Omaha, Neb.

Napier, Alex E. (J'28), Bldg. Secy., Pur. & Maint., Y.M.C.A., 167 Sands St., Brooklyn, N.Y.

Napier, David Jamieson ('45) (FKS), Canadian Rep. & Supvg. Inspr., Mutual Boiler Ins. Co. of Boston, 607 Sterling Tower, 372 Bay St., Toronto; *for mail*, 85 Esgore Dr., Toronto 12, Ont., Can.

Napier, E. T. (J'37) (BKS), Lt., U.S.N., Naval Boiler & Turbine Lab., Naval Shipyard, Philadelphia, Pa.

Napp, Anthony Edward (J'43) (BAHJS), Product & Design Engr., Arma Corp., 254—36th St., Brooklyn; *for mail*, 101 Nassau Ave., Brooklyn 22, N.Y.

Nardelli, Dominick (J'45), 576 E. 181st St., Bronx 57, N.Y.
Nardone, Pio (J'43) (SHME), Mech. Engr., Research Dept., Worthington Pump & Mchy. Corp., Worthington Ave., Harrison, N.J.; *for mail*, 1578—85th St., Brooklyn 28, N.Y.
Nardone, Romeo Morton ('34; '35) (ABMNHY), Ch. Engr., Victory Engrg. Corp., 744 Broad St., Newark 2; *for mail*, 744 River Rd., Teaneck, N.J.
Narmore, Phil Blasier ('44) (BJYCAN), Exec. Dean, Ga. Sch. of Tech., Atlanta, Ga.
Nascenzi, Frank Lawrence (J'42) (MCYJNB), Mfg. Engr., Westinghouse Elec. Corp., Bloomfield; *for mail*, 50 Morton Pl., East Orange, N.J.
Nash, Charles Whitwell (J'42) (ACHB), Pilot Officer, Royal Canadian Air Force; 1940 Greatford Pl., Victoria, B.C., Can.
Nash, Douglas E. ('17; '35), Treas., Nash Engrg. Co., Wilson Ave., South Norwalk, Conn.
Nash, Richard Leland (J'34) (CBENRS), Asst. Ch. Engr., Chicago Pneumatic Tool Co.; *for mail*, 1043 Elk St., Franklin, Pa.
Nasmyth, P. H. (J'46), 129 Adolphus St., Cornwall, Ont., Can.
Nass, Lawrence (J'41) (NJBAGY), Mech. Designer, Mch. & Tool Design Co. of N.Y., 200 Madison Ave., New York; *for mail*, 1670 E. 24th St., Brooklyn, N.Y.
Nass, Walter Robert (J'40) (BNZJH), Major, U.S.A.; *for mail*, 2033 W. 78th Pl., Los Angeles, Calif.
Nathan, Henry H. (J'34) (BSK), Assoc. Mar. Engr., Naval Shipyard, Charleston; *for mail*, 20 Glebe, Charleston 6, S.C.
Nathan, Walter (J'44) (MNC), Electronics Technician's Mate, 2nd Class, U.S.N.R., Radio Instr., Naval Trng. Sta., Navy Pier, 4th Phase, Chicago; *for mail*, 740 Bittersweet Pl., Chicago 13, Ill.
Nathanson, Max ('45), Propr., Mgr., Canadian Armature Works, 6595 St. Urbain St.; *for mail*, 5457 Victoria Ave., Montreal, Que., Can.
Natkins, Ephraim Nathaniel (J'44) (BHJ), Gries Reproducer Corp., 780 E. 133rd St., New York; *for mail*, 939 Woodycrest Ave., Bronx, N.Y.
Nau, Henry A. ('40) (MNORTY), 90 West St., New York 6, N.Y.
Nau, Paul Russell (J'38) (EFZ), Asst. Exper. Engr., Wis. Motor Corp., 1910 S. 53rd St.; *for mail*, 2164 S. 60th St., West Allis 14, Wis.
Naughton, Frank U., Jr. (J'45) (BCT), Sales Engr., Hyatt Bearings Div., Gen. Motor Sales Corp., Harrison, N.J.; *for mail*, 983 Pleasant St., Worcester, Mass.
Naughton, John Francis (J'45) (ABJ), Asst. Metallurgist, Wright Aero. Corp., Paterson; *for mail*, 292 Edgewood Ave., West Englewood, N.J.
Naugle, John J. ('24), 120 Wall St., New York, N.Y.
Naujoks, Waldemar ('44) (JCANML), Ch. Engr., Steel Improvement & Forge Co., 970 E. 64th St., Cleveland 14; *for mail*, 3804 Severn Rd., Cleveland Heights 18, Ohio.
Naulin, Donald B. (J'43) (ECMSFA), Jr. Mech. Engr., Diesel Div., Nordberg Mfg. Co., 3073 S. Chase Ave., Milwaukee 7; *for mail*, 4787 N. Idlewild Ave., Milwaukee 11, Wis.
Naumburg, Robert Elkan ('17; '24) (TLM), Mech. Engr., Jonas & Naumburg Corp., 516 W. 35th St., New York 1, N.Y.
Naylor, Franklin Llewellyn, Jr. (J'31) (CAMRJN), Co-ordinator, Charge of Interchangeability, Lockheed Aircraft Corp. & Instr., Burbank Unified Sch. Dist., Burbank; *for mail*, 1324 N. Pacific Ave., Glendale 2, Calif.

Olivetti, Dino (J'41) (MSA), Mech. Engr., Research & Devel., Diamond Instrument Co., Wakefield; *for mail,* 54 Abbot St., Andover, Mass.
Olmstead, Arthur E. (J'38) (SKF), Mar. Serv. Engr., Babcock & Wilcox Co., 85 Liberty St., New York 6; *for mail,* 34 Park St., Pulaski, N.Y.
Olofson, E. Clifford (J'35) (BCJ), Lt., U.S.N.R., 59 Shadylawn Dr., Madison, N.J.
O'Loughlin, William Henry (J'46) (CDM), 215 Douglas St., Stratford, Ont., Can.
Olowinski, Edward J. (J'45) (SKB), Research Asst., Engrg. Exper. Sta., Pa. State College, State College, Pa.
Olschner, Heinz J. (J'42) (ABFKNS), Mech. Engr., 10 Fairway Ave., Belleville 9, N.J.
Olsen, Clyde Russell (J'45) (MBNOSA), 231 N. 1st St. W., Ephraim, Utah.
Olsen, Gustav Edwin (J'20) (KMCDF), V.P., Mgr. of Sales, Fitzgibbons Boiler Co. Inc., 101 Park Ave., New York 17; *for mail,* 68-09 Beach Channel Dr., Arverne, N.Y.
Olsen, Joseph O. ('45) (NOHMBC), Pres., Productioneering Associates, 526 W. State St., Rockford, Ill.
Olsen, Leroy (J'38), Dept. of Mech. Engrg., Carnegie Inst. of Tech., Pittsburgh, Pa.
Olsen, Olaf LaCour ('24; '41) (EHKL), Owner, Firm of O. L. Olsen, 610—2nd Natl. Bank Bldg., Houston 2, Tex.
Olsen, Robert Arnold (J'42), 333 W. Stadium Ave., West Lafayette, Ind.
Olsen, Robert Carlton (J'44) (CES), 309 Sherwood Pl., Stratford, Conn.
Olson, Carlton Tropp (J'41) (EFZAM), Automotive Engr., Research & Devel. Lab., Socony-Vacuum Oil Co., Inc., Paulsboro; *for mail,* 341 Roosevelt Ave., Pitman, N.J.
Olson, Donald Richard (J'45) (KSNFAB), Instr., Mech. Engrg. Dept., Yale Univ., 400 Temple St., New Haven, Conn.
Olson, Emil (J'29) (MSCF), Supt. of Prod., Hawaiian Elec. Co., Ltd., 900 Richards St., Honolulu, T.H.
Olson, Ernest William ('29; '42) (YNLCMS), Ch. Engr., Firestone Rubber & Latex Co., 1 Firestone Ave., Fall River; *for mail,* Pearse Rd., Swansea, Mass.
Olson, F. Stuart (J'40), 6 McGrady St., Glen Cove, L.I., N.Y.
Olson, Foster A. (J'38) (CJL), Oper. Engr., N.J. Zinc Co.; *for mail,* Horse Head Inn, Palmerton, Pa.
Olson, Geo. D. ('36) (SCF), Ch. Engr., Commonwealth Edison Co., 3400 N. California Ave., Chicago 18, Ill.
Olson, Gordon Glenn (J'43) (SKE), Application Engr., Allis-Chalmers Mfg. Co., Milwaukee 1; *for mail,* 210 N. 74th St., Milwaukee 13, Wis.
Olson, Harold Thornton ('44) (CNZM), Engr., Remington Rand, Inc., 67—35th St., Brooklyn 32, N.Y.
Olson, Malven Leonard ('45) (FLCBK), Sr. Engr., Equip. Devel., Prest-O-Lite Co., Inc., Box 1478, Indianapolis 6, Ind.
Olson, Martin L. ('14; '19) (ACM), Retired; 81 West St., Hyde Park 36, Boston, Mass.
Olson, Mauritz M. (J'40) (NABEJ), Mech. Engr., Natl. Advis. Com. for Aero., Langley Field; *for mail,* 239 Raleigh Ave., Hampton, Va.
Olson, Peter G., Jr. (J'45) Foreman, Large Turbine Erection, Westinghouse Elec. Corp., Lester; *for mail,* R.F.D. 2, Media, Pa.
Olson, Raymond G., Jr. (J'44), 707 York Rd., Glenview, Ill.
Olson, Reuben M. (J'41) (SBKW), Mech. Engr., Naval Ord. Lab., Naval Gun Factory, Washington 25, D.C.; *for mail,* 6614 Hillandale Rd., Chevy Chase 15, Md.
Olson, Robert George ('43) (ESHA), East. Mgr., Hyd. Coupling Div., Am. Blower Corp., 50 W. 40th St., New York 18; *for mail,* 108 E. 38th St., New York 16, N.Y.
Olson, Robert V. ('29; '35) (CMBTJA), Pres., Gen. Mgr., Mossberg Pressed Steel Corp., West St., Attleboro, Mass.
Olson, Theodor M. (J'41) (BEM), Lt. (j.g.), U.S.N.R.; 165 Laurel Ave., North Palo Alto, Calif.
Olson, William Harry Milton (J'38) (CMDN EA), Spec. Assignments, Factory Layout, Turbine Mfg. Div., Gen. Elec. Co., 1 River Rd., Schenectady; *for mail,* 1958 Wabash Ave., Schenectady 6, N.Y.
Olsson, Charles David (J'41) (MNJY), Sales Engr., Olsson & Pierce Co., 111 Broadway, New York 6, N.Y.
Olsson, T. Karl (J'41) (BHJ), Test Engr., Ford Instrument Co., 31-10 Thompson Ave., Long Island City; *for mail,* 186-05 Ilion Ave., St. Albans 12, N.Y.
Olt, Richard Greve ('44; '44) (ZMLCJK), Devel. Engr., Optron Lab., 2655 Salem Ave.; *for mail,* 1819 Ravenwood Ave., Dayton 6, Ohio.
Olvany, William James, Jr. (J'43) (EFKS), 109-40—71st Rd., Forest Hills, N.Y.
Olver, Albert Stephen (J'29) (APR), Gen. Sales Dept., Imperial Oil, Ltd., Imperial Oil Bldg., Toronto 1, Ont., Can.
Olver, Frank Monroe (J'42) (ACJ), Asst. Stress Analyst, Glenn L. Martin Co., Baltimore; *for mail,* Box 513, Cent. Y.M.C.A., Franklin at Cathedral St., Baltimore 1, Md.
O'Mara, Edward Andrew (J'38), Lt., U.S.N., Washington, D.C.; *for mail,* 78 Central Ave., Montclair, N.J.
O'Mara, Richard F. ('28; '37) (LSCF), Sales Mgr., West. Precipitation Corp., 1016 W. 9th St., Los Angeles 15, Calif.
Omelianoff, Geo. M. (J'38) (NHACDG), Estimating Engr., Progressive Welder Co., 3050 E. Outer Dr., Detroit 12; *for mail,* 15 Bartlett St., Detroit 3, Mich.
Onderdonk, Paul Truman ('27; '35) (SHC), Inspc. Engr., Consltd. Edison Co. of N.Y., Inc., 4 Irving Pl., New York 3; *for mail,* 204 Kensington Rd., Garden City, N.Y.
Ondr, Joe Oliver, Jr. (J'44) (AW), 67 Ridgemoor Dr., Clayton 5, Mo.
O'Neil, Frederick William ('01; '08), V.P. & Ch. Engr., Ingersoll-Rand Co., 11 Broadway, New York 4, N.Y.; *for mail,* Oklawaha, Marion Co., Fla.
O'Neil, John Francis (J'41) (ABC), Sales Engr., Busch-Sulzer Bros.-Diesel Eng. Co., 3300 S. 2nd, St. Louis; *for mail,* 819 S. Gray Ave., Webster Groves 12, Mo.
O'Neil, Robert Dravo ('27; '36) (EFZOHK), Engr., Am. Meter Co., Inc., 1104 Watts Bldg., Birmingham 3, Ala.
O'Neill, George W. ('28; '34) (DFS), Maj., Petawawa Military Camp, Petawawa, Ont., Can.
O'Neill, James Lawrence ('42) (CMOD), Indus. Engr., Geo. Scher Engrg. Co., 115—1st St., Newark 7; *for mail,* 78 Pennington Ave., Passaic, N.J.
O'Neill, Theodore (J'43) (YDC), Field Engr., Goodyear Tire & Rubber Co. of Can., Ltd., New Toronto; *for mail,* 69 Canning Ave., Islington, Ont., Can.
O'Neill, William Charles, III (J'43) (CRS), U.S. Navy; Huntington Valley, Pa.
Onsrud, Rudolph F. ('35) (WNJCA), Pres., Gen. Mgr., Onsrud Mch. Works, Inc., 3900 Palmer St., Chicago 47, Ill.
Onuf, Bronis R. (J'44) (KEBS), Instr., Yale Univ., 400 Temple St., New Haven 11, Conn.
Oonk, Rowland George (J'45), Ford Motor Co., 5410 Orchard St., Dearborn; *for mail,* 11832 Ohio, Detroit 4, Mich.
Oonk, William Joseph ('22; '37) (SWKDRL), Dist. Application Engr., B. F. Sturtevant Co., Div. of Westinghouse Elec. Corp., 411 N. 7th St., St. Louis 1; *for mail,* 4548 Red Bud Ave., St. Louis 15, Mo.
Oosten, Louis Stanley (J'44) (BHK), Asst. Ch. Engr., Bell & Gossett Co., Morton Grove; *for mail,* 725 Case St., Evanston, Ill.
Opatowski, I. ('40) (BWAKHJ), Research Staff Member, Univ. of Chicago, 5822 Drexel Ave., Chicago 37; *for mail,* 1047 W. North Shore Ave., Chicago 26, Ill.
Openshaw, Arthur Benson ('46) (FKS), Dist. Mgr., Combustion Engrg. Co., Inc., 2330 Bankers Bldg., Chicago 3, Ill.
Ophuls, Fred ('14) (EFKOS), Owner, Fred Ophuls & Associates, 112 W. 42nd St., New York 18, N.Y.
Opila, Francis Anthony (J'43) (BCZJMR), Asst. Supt. of Southwark Div., Baldwin Loco. Works, Eddystone; *for mail,* 101 Gladstone Rd., Lansdowne, Pa.
Opkins, Jerold Stanley (J'43) (ASNMER), 1st Lt., Corps of Engrs., U.S.A., Supply Officer, 496th Engr. Heavy Shop Co., Gp. III, Army Serv. Forces Trng. Center, Ft. Belvoir, Va.
Opp, George C. A. ('42) (SCOMFR), Safety Consultant, Detroit Edison Co., 2000—2nd Ave., Detroit 26; *for mail,* 20144 Renfrew Rd., Detroit 21, Mich.
Oppenheimer, Arthur C., II (J'41) (BCE), Lt. (j.g.), Ord. Officer, c/o Asst. to Indus. Mgr., U.S.N., Box 1423, Mobile; *for mail,* Spring Hill, Ala.
Oppenheimer, Edwin Adam ('28; '34; '35) (SF LDKC), M.M., Penick & Ford Ltd., Inc., Cedar Rapids, Iowa.
Oppenheimer, Philip H. ('27; '35) (FKLOSZ), Cons. Engr., 225 E. Broad St., Westfield, N.J.
Opsahl, Emil ('42; '45) (DNCS), Mech. Engr., Link-Belt Co., Ltd., 791 Eastern Ave., Toronto, Ont., Can.
Oquendo, Raul (J'41) (CHS), Ulacia, S.A., Central Ulacia, Rodrigo, Provincia de las Villas, Cuba.
Oran, Samuel (J'45) (BMO), Mech. Designer, Barnes & Reinecke, 230 E. Ohio St., Chicago 11; *for mail,* 5804 W. Catalpa, Chicago 30, Ill.
Orban, Alex Richard (J'42) (ABJ), Mech. Engr., Dowmetal Engrg. Lab., Dow Chem. Co.; *for mail,* 322 N. Lincoln Ave., Bay City, Mich.
Orbeck, Einar Melvin ('27; '37) (MNACJ), Mech. Designer, Hamilton Stand. Propellers Div., United Aircraft Corp., East Hartford 8; *for mail,* 9 Linnard Rd., West Hartford 7, Conn.
Orcutt, Arthur Hitchcock ('36) (NHC), Managing Dir., Gear Grinding Co. Ltd., Cranmore Blvd., Shirley, Birmingham; *for mail,* Rowington Hall, Nr. Warwick, England.

Ordway, Earl P. ('14; '17), Pres., Union Steam Pump Co.; *for mail,* 151 Emmett St., Battle Creek, Mich.
O'Regan, William Frederick ('42) (SFEG), Mech. Inspr., c/o Supvr. of Shipbldg., U.S.N., Quincy; *for mail,* 23 Crockett Ave., Dorchester 22, Mass.
Oren, Jess William, III (J'45), Research Asst., Pa. State College, Box 436, State College; *for mail,* 307 N. George St., Pottsville, Pa.
Orenstein, Hartwig ('22) (OMCDJW), Cons. Engr., 140 Queen's Drive, Glasgow, S. 2, Scotland.
Orent, Edward (J'44), Layout Draftsman, Detroit Transmission Div., Gen. Motors Corp., 5140 Riopelle, Detroit; *for mail,* 523 Crosby St., Grand Rapids 4, Mich.
Oreskovich, Peter Joe (J'41) (ONBJEM), Pres., Oreskovich & Co., Louisville Trust Bldg., Louisville 2; *for mail,* 1000 Oakwood Ave., Louisville 8, Ky.
Orlando, Patrick Joseph (J'46) (BFK), 2209 Dietz Pl., North Bergen, N.J.
Orloff, Serge ('42; '44) (NBMC), Ch. Design Engr., Am. Chain & Cable Co. Inc., 1575 S. 6th St., Camden, N.J.
Ormond, Alex C. (J'40) (OSACMJ), Draftsman, Union Bag & Paper Corp.; *for mail,* 102 E. 44th St., Savannah, Ga.
Ormond, Alex. M. ('23) (CFL), Engr., Savannah Sugar Refining Corp.; *for mail,* 102 E. 44th St., Savannah, Ga.
Ormondroyd, Jesse ('31) (BEHASR), 2104 Copley Ave., Ann Arbor, Mich.
Ormston, Alfred J. (J'39) (AKS), Jr. Engr., Plant Constr. Dept., Fla. Power Corp.; *for mail,* 337-8th St. N., St. Petersburg, Fla.
Orning, Arthur Alonzo ('45) (FKSE), Mem. Staff, Coal Research Lab., Carnegie Inst. of Tech., Schenley Park, Pittsburgh 13, Pa.
Orno, Knud E. ('27) (CLNT), Mgr., Engrg. Sec., Rayon Div., E. I. du Pont de Nemours & Co., Wilmington; *for mail,* Apt. C-205, 1300 Harrison St., Wilmington 12, Del.
O'Rourke, Hugh Dominic, Jr. (J'38) (KS), B. F. Sturtevant Div., Westinghouse Elec. Corp., 812 Mich. Theatre Bldg., Detroit 26, Mich.
O'Rourke, John Thomas (J'46) (GJ), 530 Vidal Dr., Parkmerced, San Francisco, Calif.
O'Rourke, Patrick Edward ('41) (ABCES), Pres., O'Rourke & Royer Inc., 740 Gas & Elec. Bldg., Denver 2, Colo.
Orr, Alexander Macklin ('98; '23), Retired; Box 311, Edgartown, Mass.
Orr, Carol Lister ('21; '23; '29) (CLSFKH), Power Plant Mgr., Tex. Gulf Sulphur Co., Newgulf, Tex.
Orr, Claud Henry ('19; '26) (CMD), Supt., Natl. Carbon Co. Inc., Box 749, Charlotte 1, N.C.
Orr, Fred B. ('21) (FSYAE), Retired; 1618 Sunset Plaza Dr., Los Angeles 46, Calif.
Orr, Howard S. (J'32) (JB), Turn Foreman, Carnegie-Ill. Steel Corp., N. Buchanan; *for mail,* 444 Marshall St., Gary, Ind.
Orr, J. L. ('41), 920 E. Haines St., Philadelphia 38, Pa.
Orr, John ('09), Prof. Engrg., 14 Hyde Park Mansions, Park Lane, Parktown, Johannesburg, S. Africa.
Orr, Leighton ('44) (ABK), Research Engr., Research Lab., Pittsburgh Plate Glass Co., Creighton; *for mail,* 1116 Cambridge St., Tarentum, Pa.
Orr, Wesley Leland ('44) (BONCH), Assoc. Prof. Engrg., Univ. of Calif. at Los Angeles, 405 Hilgard Ave., Los Angeles 25; *for mail,* 728—23rd St., Santa Monica, Calif.
Orr, William Austin (J'42) (AJSNMC), Engr., U. S. Maritime Serv., War Shipping Admin., Washington, D.C.; *for mail,* 3914 Lindell Blvd., St. Louis 8, Mo.
Orr, William R. (J'41) (ACJ), N.A.T.S.-Pacific, Navy 29, F.P.O., San Francisco, Calif.
Orrell, John E. ('34; '43) (MESZJC), Mech. Engr., Shell Oil Co., Inc., Box 2010, Wichita Falls, Tex.
Orrok, George A., Jr. ('31; '39) (SKBFHJ), Acting Asst. Supt. of Engrg., Boston Edison Co., 39 Boylston St., Boston 12; *for mail,* 5 Cleveland St., Cambridge 38, Mass.
Orsini, Anthony (J'42) (MLAS), Devel. Engr., Walter Kidde & Co., 675 Main St., Belleville 9; *for mail,* 122—65th St., West New York, N.J.
Orskog, Arthur Gordon (J'45) (FKO), Canadian Ice Mch. Co., 65 Villiers St., Toronto 2, Ont., Can.
Orth, Harry R. (J'46) (SYZ), 3131 Forest, Kansas City, Mo.
Ortla, Frederick L. ('27), 25 Belvoir Rd., Milton, Mass.
Ortman, Hadar ('30; '35) (CG), V.P., McClure, Hadden & Ortman, Inc., 111 W. Washington St., Chicago, Ill.

Rabinow, David ('44) (CMNDH), Ch. Engr., Conmar Products Corp., 140 Thomas St., Newark 1; *for mail,* 41 Tuscan Rd., Maplewood, N.J.
Raborg, Joseph H. (J'42), Application Engr., Worthington Pump & Mchy. Corp., Harrison, N.J.; *for mail,* 601 Eagle Ave., New York 55, N.Y.
Rach, J. Louis W. ('19; '35), Mech. Engr., Design, Bartlett Hayward Div., Koppers Co., Scott St.; *for mail,* 1947 E. 31st St., Baltimore, Md.
Rachals, Richard ('39; '45) (CN), Engr., Gibbs & Cox, Inc., 21 West St., New York 6, N.Y.
Radach, Paul Reinhardt (J'43) (NACM), Specialist, U.S.N.R., Mech. Engr. (Design), Div. N, Ames Aero. Lab., Natl. Advis. Com. for Aero., Moffett Field, Calif.
Radamaker, George Lewis (J'43) (SLCMOK), Mch. Designer, Spec. Equip., Spring Div., Eaton Mfg. Co., 9771 French Rd.; *for mail,* 8050 Dobel St., Detroit 5, Mich.
Radcliff, Leo Lewis (J'41) (SOLMDE), Mech. Engr., Devel., Corn Products Refining Co., Argo, Ill.
Radcliffe, John C., III (J'39), Trans. Sales, Westinghouse Elec. Corp., 411 N. 7th St., St. Louis 1; *for mail,* 221 E. Jefferson Ave., Kirkwood 22, Mo.
Radden, Charles O. (J'36) (ES), Indus. Serv. Engr., Gulf Oil Corp., Park Sq., Boston; *for mail,* 18 Miami Ave., West Roxbury 32, Mass.
Radeck, Justin E. (J'38) (BEHJN), Engr., Salesman, Cameron Iron Works, 5125 Santa Fe St., Los Angeles 14, Calif.
Radecki, Michael J. ('30; '35) (CMBJKL), Supt., Henry G. Thompson & Son Co., 277 Chapel St., New Haven 5, Conn.
Rader, Donald Arlie (J'42) (AMNB), Engr., Layout Design, Airplane Div., Curtiss-Wright Corp., 4300 E. 5th Ave., Columbus 16; *for mail,* 851 Kenwick Rd., Columbus 9, Ohio.
Radford, G. S. ('15; F'41) (MTW), Cons. Engr., Box 426, New Canaan, Conn.
Radinse, Carl H. (J'39) (BNMH), Engr., Mfrs. Brush Co., 12501 Elmwood Ave., Cleveland 11, Ohio.
Radziminski, Whitold Wladislaw ('44) (MNRSZ), Designer, Engrg. Dept., E. I. du Pont de Nemours & Co.; *for mail,* 703 W. 22nd St., Wilmington, Del.
Rae, Otis Ott ('44) (CKMORS), Mgr., Southeast. Cent. Sta., Westinghouse Elec. Corp., 1299 Northside Dr., N.W., Atlanta, Ga.
Raech, Harry, Jr. (J'44) (ZNL), Devel. Engr., Natl. Electronics Corp., 3141 W. 110th St., Cleveland; *for mail,* 367 South Island, Rocky River, Ohio.
Raess, Theodore F. (J'42) (SKEJ), Engr., Diesel Devel. Dept., Joshua Hendy Iron Works, Sunnyvale; *for mail,* Box 142, Palo Alto, Calif.
Raettig, Alvin Ernest, Jr. (J'40) (N), 213 Winona Dr., Decatur, Ga.
Raetz, Gibbs Stanley (J'42) (ACE), Flight Test Analyst, Lockheed Aircraft Corp., Burbank; *for mail,* 1553 N. Stanley Ave., Los Angeles 46, Calif.
Raetz, Stephen James ('21) (CR), Supvr., Cars & Shops Maint., Independent Div., N.Y.C. Transit System, 3961—10th Ave., New York 34; *for mail,* C-42, Hudson View Gardens, 183rd St. & Pinehurst Ave., New York 33, N.Y.
Ragsdale, Earl J. W. ('45) (RGAJ), Ch. Engr., Ry. Div., Edw. G. Budd Mfg. Co., 2450 Hunting Park Ave., Philadelphia 32, Pa.
Rahikka, Reino Erick (J'43) (CMA), Equip. Engr., West. Elec. Co., Inc., 100 Central Ave., Kearny; *for mail,* 148 Orient Ave., Jersey City 5, N.J.
Rahm, Fenton D. ('23) (CEHL), Mgr., Houston Office, A. M. Lockett & Co. Ltd., 808 Elec. Bldg., 1016 Walker Ave., Houston 2, Tex.
Rahm, Frederick W. ('38) (MLJCB), Designer, Geo. Scher Engrg. Co., 1st St., Newark, N.J.; *for mail,* Greene Pl., New York, N.Y.
Rahm, Louis Frank ('23; '34) (Y), Assoc. Prof. Mech. Engrg., Sch. of Engrg., Princeton Univ., Princeton, N.J.
Rahm, Robert Carl ('42) (BNY), Treas., Ch. Engr., Berks Engrg. Co., 6th & Chestnut Sts., Reading, Pa.
Raife, Archie (J'44) (BCGJMN), Mech. Engr., Stewart-Warner Corp., 1826 Diversey Pky., Chicago 14; *for mail,* 5749 N. Central Park, Chicago 45, Ill.
Raimondi, Albert Anthony (J'46), Ensign, U.S.N.R., U.S.S. *Renville,* A.P.O. 227, F.P.O., San Francisco, Calif.; *for mail,* 25 Crescent St., North Plymouth, Mass.
Rainesalo, Charles Ilmari ('38) (SEM), Ch. Engr., Ajax Iron Works, 26 W. Washington St.; *for mail,* 152 Park St., Corry, Pa.
Raisch, William ('24; '34) (LO), Cons. Engr., 227 Fulton St., New York 7, N.Y.
Raisig, Charles L. ('18; '35) (BJM), Ch. Engr. of Sales, Mesta Mch. Co., Pittsburgh; *for mail,* Park Hill, R.D. 1, Coraopolis, Pa.
Raisler, Herbert (J'37) (CK), Engr., Raisler Corp., 129 Amsterdam Ave.; *for mail,* Apt. 16-B, 49 E. 96th St., New York, N.Y.
Raisler, Robert K. ('26; '33; '35) (OKESCA), Treas., Raisler Corp., 129 Amsterdam Ave., New York 23, N.Y.
Raitt, George H. ('21; '28) (C), Pres., Gen., Mgr., Steel Tank & Pipe Co. of Calif., 1100—4th St., Berkeley 5, Calif.
Raju, C. S. N. ('27; '34; '35), Deputy Indus. Adviser, "N" Block, Raisina Rd., New Delhi, India.
Rakatansky, Harold (J'40) (BES), U.S. Army; 52 Gladstone St., Providence, R.I.
Raley, Ray E., Jr. (J'45) (P), Box 197-X, Route 1, Bakersfield, Calif.
Rall, Charles Otto (J'30) (CMS), Prod. Engr., Pittsburgh Piping & Equip. Co., 10—43rd St., Pittsburgh 1; *for mail,* 210 Amber St., Pittsburgh 6, Pa.
Rall, Edwin Beresford ('41) (CFOSR), Asst. Plant Engr., Detroit Edison Co., 2000—2nd Ave., Detroit 26; *for mail,* 1344 Yorkshire Rd., Grosse Pointe Park 30, Mich.
Ralph, John Roger (J'44) (SDAR), Mech. Engr., Draftsman, Austin Co., 16112 Euclid Ave., Cleveland; *for mail,* 14737 Lorain St., Cleveland 11, Ohio.
Ralston, Alexander Hoyle ('45) (HOS), W. M. Anderson Co., 600 Schuylkill Ave., Philadelphia; *for mail,* 2452 Eldon Ave., Drexel Hill, Pa.
Ralton, Francis Arthur ('22; '23) (SKFHCT), Designing Engr., Am. Woolen Co. Inc., 1 Mill St., Lawrence, Mass.
Ram, R. Anant, Sr. ('30; '34; '35) (MST), Ch. Mech. & Elec. Engr., Hira Mills, Ltd., Ujjain, Gwalior, Central India.
Ramage, Edwin C., Jr. ('22; '27; '32) (CFL), Pinehurst Farms, Route 3, Maryville, Tenn.
Ramage, Raymond William (18; '26; '35) (NJYMR), Instr. in Mch. Design, Tech. Dept., North High Sch., E. Frederick St.; *for mail,* 71 Homer St., Binghamton, N.Y.
Ramaswami, E. K. ('29), Prof., College of Engrg., Bangalore, S. India.
Ramberg, Walter ('36) (ABJ), Sr. Physicist, Natl. Bur. of Stands., Dept. of Commerce, Connecticut Ave. at Upton St., Washington 25, D.C.
Rambo, Harold Edwin (J'42), Engr., Cardox Corp., Monee; *for mail,* 3706 Union Ave., Steger, Ill.
Ramey, John Randolph, Jr. (J'45) (HOZADN), Asst. Project Engr., U.S. Waterways Exper. Sta., Vicksburg; *for mail,* Box 35, West, Miss.
Ramey, Roy H. ('39), Serv. Engr., R.D. Div., Worthington Pump & Mchy. Corp., 224 Townsend St., San Francisco, Calif.
Ramirez, S. John (J'43) (LSKYFD), Asst. Ch. Draftsman, S. D. Hicks & Son, 1671 Hyde Park Ave., Boston 36; *for mail,* 22 Suffolk Ave., Revere 51, Mass.
Ramm, Henry F. ('36; '38) (AHL), Prod. Engr., Pratt & Whitney Aircraft Div., United Aircraft Corp., East Hartford; *for mail,* R.F.D. 1, Columbia, Conn.
Ramsay, Erskine ('25), Chmn. of Bd., Gen. Cons. Engr., Ala. By-Products Corp., 1915—1st Natl. Bldg., Birmingham 3, Ala.
Ramsay, W. A. ('17), Pres., W. A. Ramsay, Ltd., Box 1721, Honolulu, T.H.
Ramsdell, Roger Gibbs, Jr. (J'41) (SHK), Engrg. Asst., Consltd. Edison Co. of N.Y., Inc., 4 Irving Pl., New York 3; *for mail,* 28 Walnut Ave., Rockville Centre, N.Y.
Ramsden, John T. ('06) (ABCHJK), Exec. Ch. Engr., Tabor Mfg. Co., 6225 Tacony St., Philadelphia; *for mail* 1911 N. 17th St., Philadelphia 21, Pa.
Ramsey, Clifford Houston ('20) (BCY), Pres., John Royle & Sons, 10 Essex St., Paterson 3, N.J.
Ramsey, George ('16) (J), Partner, Ramsey, Kent & Chisholm, 11 Park Pl., New York 7, N.Y.
Ramsey, Justin Houston ('44) (YNJRKL), V.P., Sales & Engrg., John Royle & Sons, 10 Essex St., Paterson 3, N.J.
Ramson, John Richard, Jr. (J'42), Design Engr., Iowa Mfg. Co.; *for mail,* 1501—6th Ave., S.E., Cedar Rapids, Iowa.
Ranck, Clayton Ernst (J'41) (DLM), Ensign, U.S.N.R.; *for mail,* 212 St. Mark's Sq., Philadelphia 4, Pa.
Rand, Irvin Jerome ('45) (SHLKEO), Sales Engr., Ingersoll-Rand Co., 224 E. 9th St., Cincinnati 2; *for mail,* 3245 Orion Ave., Cincinnati 13, Ohio.
Rand, William Arthur (J'42) (MAJCBD), Ensign, U.S.N.R., LSM-283, F.P.O., San Francisco, Calif.
Randall, Guy B. ('22) (FLS), Cons. Engr., Champion Paper & Fibre Co.; *for mail,* 851 Gray Ave., Hamilton, Ohio.
Randall, John Foster (J'36) (JKFS), Engr., Automotive Research Dept., Ford Motor Co., Village Rd. Bldg., Dearborn; *for mail,* 14516 Terry Ave., Detroit 27, Mich.
Randall, Merwyn C. ('40), Sr. Engr., Philadelphia Elec. Co., 17th Floor, Edison Bldg., 9th & Sansom St., Philadelphia; *for mail,* 6211 Jefferson St., Philadelphia 31, Pa.
Randall, Ross D. ('31; '45) (BKM), Dept. 239, Stewart-Warner Corp., Indianapolis, Ind.
Randich, Erasmus A. (J'43) (MJBYDL), Design Draftsman, Plant Engrg. Dept., Bethlehem Steel Co.; *for mail,* 302 E. Broad St., Bethlehem, Pa.
Randle, Winslow Allhands (J'39), 1st Lt., Corps of Engrs., U.S.A., Co. A, 47th Div.; *for mail,* Port Sulphur, La.
Randolph, Frank Harrison ('22; '32) (KFOSCG), Prof. Hotel Engrg., Cornell Univ., Box 55, Roberts Hall, Ithaca, N.Y.
Raney, Russell Raymond ('45) (BCH), Asst. Ch. Engr., McCormick Works, Internatl. Harvester Co., 26th & Western Ave., Chicago 8, Ill.
Rang, Eugene ('30; '35) (S), Boiler Inspr., Hartford Steam Boiler Inspc. & Ins. Co., 56 Prospect St., Hartford; *for mail,* 466 Main St., Norwich, Conn.
Raninen, Arnold Birchard (J'44) (BMNJ), Engr., Ord. Design, Aberdeen Proving Ground; *for mail,* 228 Seneca Ave., Havre de Grace, Md.
Rank, Homer Lee ('18; '22) (FSD), Sales Mgr., Pulverizer Dept., Strong Scott Mfg. Co., Northwest. Terminal, Minneapolis 13; *for mail,* 7040 Oak Grove Blvd., Minneapolis 9, Minn.
Rankel, Robert A. (J'40) (LEARZS), Research Engr., Anemostat Corp. of Am., 10 E. 39th St., New York; *for mail,* 55 Baisley Ave., East Rockaway, L.I., N.Y.
Ranken, Howard B. ('29; '31) (BLOJHY), Professional Engr., Land Surveyor, Box 202, Edgewater, Fla.
Rankin, Andrew William ('45) (BSJN), Turbine-Generator Engrg. Div., Gen. Elec. Co., Schenectady, N.Y.
Rankin, Charles John ('45) (MJKCOS), Exec., Robert A. Rankin & Co., 1420 Sherbrooke St. W., Montreal, Que., Can.
Rankin, Charles Rule (J'45) (CBHAM), Lab. Engr., Caterpillar Tractor Co., Peoria 8; *for mail,* 526 Linn St., Peoria 5, Ill.
Rankin, Dan Richart ('45) (BHJ), Ch. Engr., Peerless Pump Div., Food Mchy. Corp., 301 W. Ave. 26, Los Angeles 31; *for mail,* 5310 Aldama St., Los Angeles 42, Calif.
Rankin, Robert Arthur ('40) (LOCSFD), Pres., Robert A. Rankin & Co., 1420 Sherbrooke St. W., Montreal, Que., Can.
Rankin, Robert L. (J'40) (EF), Jr. Mech. Engr., Shell Oil Co., Inc., 965—1st Natl. Bldg., Oklahoma City, Okla.
Ranney, Leo ('40) (EFH), Pres., Gen. Mgr., Ranney Oil Mining Co., Box 67, Morro Bay, Calif.
Ransdell, Clifford Howell (J'45) (BM), Asst. Prof., Engrg. Drawing Dept., Texas Agric. & Mech. College, Box 202 F.E., College Station, Tex.
Ransohoff, Nathan ('12; '21) (LKMRSW), Pres., N. Ransohoff, Inc., Township St., Elmwood P.O., Cincinnati; *for mail,* 3509 Biddle St., Cincinnati 20, Ohio.
Ransom, J. Frederick ('35; '44) (SBEZK), Turbine Engr., Rocky Mountain Dist., Gen. Elec. Co., Box 2331, Denver 1; *for mail,* 2531 Clermont St., Denver 7, Colo.
Ransom, John Parke (J'42), 2nd Lt., Corps of Engrs., A.P.O. 702, c/o Postmaster, Seattle, Wash.
Ransom, R. Lanning ('42) (HBCNMZ), V.P., Gen. Mgr., High Pressure Pump Corp., 620 Brooks Bldg., Wilkes-Barre; *for mail,* 26 E. Walnut St., Kingston, Pa.
Ransom, W. G. ('17), Partner, Cook & Ransom, Ottawa; *for mail,* Homewood, Kan.
Ranstead, Norman H. ('27) (KL), Designing Engr., Universal Oil Products Co., 310 S. Michigan Ave., Chicago; *for mail,* 2154 Thornwood Ave., Wilmette, Ill.
Rao, Thagarthi Nagesha (J'45), Maint. Engr., Mysore Chemicals Fertilisers, Ltd., Vanivilas Rd.; *for mail,* Belagula, Mysore, India.
Rapp, John William (J'42) (BJM), Asst. M.M., Foote Bros. Gear & Mch. Corp., 4545 S. Western Blvd.; *for mail,* 6907 S. Harper Ave., Chicago, Ill.
Rapp, Philip Crowe (J'45) (BER), Project Engr., Houde Engrg. Div., Houdaille Hershey Corp., 537 E. Delavan Ave., Buffalo 11; *for mail,* 965 West Ave., Buffalo 13, N.Y.
Rardon, Norman Charles ('44) (REZASF), Engr., Loco. Equip. Div., Manning, Maxwell & Moore, Inc., 1257 Little Bldg., 80 Boylston St., Boston 16; *for mail,* 33 Hobomack Rd., Quincy 69, Mass.
Rashevsky, Michael ('44) (BSJN), Mech. Design Engr., Westinghouse Elec. Corp., 700 Braddock Ave., East Pittsburgh; *for mail,* 1506 Foliage St., Pittsburgh 21, Pa.

Raskin, Franz Joseph M. ('44) (FKEHZL), Pres., Mgr., F. J. Raskin Inc., 370 Rachel St. E., Montreal 18; *for mail,* 2620 Pie IX Blvd., Montreal 4, Que., Can.
Rasmussen, Carl Arthur (J'39) (MCNLSA), Process Engr., Prod. Engrg. Dept., Wright Aero. Corp.; *for mail,* 566—21st Ave., Paterson 3, N.J.
Rasmussen, Find ('13) (BJH), Retired; 7807—12th Ave., Brooklyn 28, N.Y.
Rasmussen, Frank ('30) (DBJRM), Dist. Engr., Link-Belt Co., 300 W. Pershing Rd., Chicago 9; *for mail,* 735 Judson Ave., Evanston, Ill.
Rasmussen, Harold V. ('23; '30) (BES), De Laval Steam Turbine Co.; *for mail,* Cadwaleder Apts., 640 W. State St., Trenton 8, N.J.
Rasmussen, Monrad Harvey (J'41) (JBAMDC), Ensign, U.S.N.R.; 3812 N. Troy St., Chicago 18, Ill.
Rasmussen, Murlin Albert (J'43) (ASMOEF), 3824 N. Calispel, Spokane 12, Wash.
Rasmussen, Roy A. (J'39) (CDFKZ), Asst. Supt., Lone Star Cement Corp., 1217—1st Natl. Bank Bldg., Dallas; *for mail,* 2759 Overcrest, Dallas 11, Tex.
Rasmusson, William Elmo (J'43) (SHBKZ), Sr. Design Engr., Oldsmobile Div., Gen. Motors Corp., Townsend St., Lansing; *for mail,* 302 Leslie St., Lansing 12, Mich.
Ratcliff, Vern H. (J'34) (SHFC), Ch. Engr., Englewood Y.M.C.A., 6545 S. Union Ave., Chicago 21, Ill.
Ratcliffe, Frank Damon ('45) (CEFHS), Dist. Mgr., Oil Industry Sales, Fairbanks, Morse & Co., 1335 Hunt Bldg., Tulsa 3, Okla.
Ratcliffe, Fred'k R. ('22) (CDM), Cons. Engr., 36 Woodside Ave., Strathfield, Sydney, New South Wales, Australia.
Rath, Robert Earle (J'46), 200 Park Ave., Swarthmore, Pa.
Rathaus, Joseph T. (J'46) (ABO), Dynamic Test Engr., Chance-Vought Aircraft Div., United Aircraft Corp.; *for mail,* 268 West Ave., Stratford, Conn.
Rathbone, Thomas Cosnett ('29) (BSEH), Ch. Engr., Mchy. Div., Fidelity & Casualty Co. of N.Y., 80 Maiden Lane, New York 7; *for mail,* 5-H, 2 Grace Court, Brooklyn 2, N.Y.

Schiller, Frank Mathew (J'43) (AEM), 324 Cooper St., Utica 2, N.Y.
Schiller, William Alfred ('20; '35) (CDJLMW), Indus. Engr., 2320 W. 25th St., Los Angeles, Calif.
Schilling, Bernhard John ('22; '35) (EF), Pres., Mgr., Newburgh Oil Co., Inc., Box 349, Newburgh, N.Y.
Schilling, William Henry (J'44) (MBCKLD), Dist. Engr., De Vilbiss Co., 1280 W. Washington Blvd., Chicago 7; *for mail,* 8701 Austin Ave., Morton Grove, Ill.
Schillinger, Christian ('22) (FKSB), Pres., Coxe Stoker Engrg. Co., 1109 Markle Bank Bldg., Hazleton, Pa.
Schimpf, Arthur James Dyer (J'43) (EKNSC), Lt. (j.g.), U.S.N.R.; *for mail,* Demarest Ave., West Nyack, N.Y.
Schimpf, Frederick John, Jr. (J'39) (BEARSZ), Diesel Test Engr., Baldwin Loco. Works, Eddystone; *for mail,* 662 S. Highland Ave., Merion Station, Pa.
Schindeler, John William, Jr. (J'45) (SEFKNB), Test & Field Engr., Buell Engrg. Co., Inc., 70 Pine St., New York 5, N.Y.; *for mail,* 802 Park Ave., Hoboken, N.J.
Schindler, Alma Johann ('44) (NMBSHR), Designing Engr., Christensen Mch. Co., Salt Lake City; *for mail,* 2900 Kenwood St., Salt Lake City 5, Utah.
Schindler, David Blair (J'39) (CJM), Application Engr., B. F. Sturtevant Co., Div. of Westinghouse Elec. Corp., 1506—1st Natl. Bank Bldg., Pittsburgh; *for mail,* 1414 Tolma Ave., Pittsburgh 16, Pa.
Schindler, Leon W. (J'43) (BSA), Mech. Engr., Gustin-Beacon Mfg. Co., 1412 W. 12th St., Kansas City 7; *for mail,* 4746 Bernice St., Kansas City 3, Kan.
Schinnerer, Roy Louis (J'39) (ANBHKJ), Design Engr., Airesearch Mfg. Co., 9851 Sepulveda Blvd., Los Angeles 45; *for mail,* 1559 Linden Ave., Long Beach 6, Calif.
Schirokauer, Henry ('44) (BCMLNH), V.P., Shirgun Corp., 136 W. 52nd St., New York 19, N.Y.
Schlachter, Carl H. ('06), Retired; 12 Crestmont Rd., Montclair, N.J.
Schlack, Bruno ('38), Engr., Philadelphia Elec. Co., Edison Bldg., 9th & Sansom Sts., Philadelphia; *for mail,* 1415 Robinson Ave., Manoa, Upper Darby, Pa.
Schlafke, Albert Paul, Jr. (J'44) (RS), Ensign, U.S.S. *Minneapolis,* CA-36, F.P.O., San Francisco, Calif.; *for mail,* 238—94th St., Brooklyn 9, N.Y.
Schlage, Ernest L. (J'38) (BJMZ), Supvr. Devel. Engrg., Librascope, Inc., 133 E. Santa Anita Ave., Burbank; *for mail,* 808 Burlingame Ave., Burlingame, Calif.
Schlanger, Arthur Lee (J'45), Jr. Engr., Clinton Engr. Works, Tenn. Eastman Corp.; *for mail,* Rm. 236, Clayton Hall (M-7), Oak Ridge, Tenn.
Schlatter, Hugo (J'41) (BLM), Design Engr., Hercules Powder Co., Port Ewen; *for mail,* 197 Bruyn Ave., Kingston, N.Y.
Schlatter, Rudolf ('10) (BEK), Ch. Mech. Engr., Busch-Sulzer Bros.-Diesel Eng. Co., 3300 S. 2nd St., St. Louis 18, Mo.
Schlatter, Rudolph Paul (J'39) (EBCFAJ), Mech. Engr., Serv. Dept., Busch-Sulzer Bros.-Diesel Eng. Co., 3300 S. 2nd St., St. Louis 18; *for mail,* 3955 Connecticut St., St. Louis 16, Mo.
Schlatter, Willard F. (J'42) (CMS), Ensign, U.S.N.R.; 3955 Connecticut St., St. Louis 16, Mo.
Schleser, Erich (J'36) (ZLHKSE), Design Engr., Pan Am. Refining Corp.; *for mail,* Box 927, Texas City, Tex.
Schlesinger, Georg C. ('05) (BCDJLM), Consultant, 145 Ashby Rd., Loughborough, Leics, England.
Schlichter, Frederick William ('37) (BCM), Pres., Ch. Engr., Works Mgr., Hamilton Tool Co., 9th & Hanover Sts.; *for mail,* RR. 4, Hamilton, Ohio.
Schlick, Louis Frederick ('40), Lt. Comdr., E-M, U.S.N., c/o Postmaster, New York, N.Y.; *for mail,* 115 Morse Ave., Rutherford, N.J.
Schlieder, Harold Augustus ('42) (SBHJKZ), Engr., No. Equip. Co., 1945 Grove Dr.; *for mail,* 632 Sassafras St., Erie, Pa.
Schlieper, E. Jerome (J'44) (MDNCWJ), Prod., Design & Maint. Engr., Union Iron Works, 600 E. William, Decatur 30, Ill.
Schlink, Frederick John ('17; '19; '24) (ZFBK), Tech. Dir., Consumers' Research, Inc., Washington, N.J.
Schlink, Norman H. (J'40) (MD), Waterford, Conn.
Schlitt, J. L. ('19; '41) (SK), Petroleum Chemicals, Inc., Box 1637, Baltimore; *for mail,* 112 Park Dr., Catonsville 28, Md.
Schlitzkus, Robert Frederick (J'39) (MNCBYZ), Ch. Engr., Prod. Engrg. Co., 9th & Dwight Way, Berkeley, Calif.
Schlobach, George F. (J'35) (CJM), Supvr. Plant Maint., Plant 4, Internatl. Business Mchs. Corp.; *for mail,* 15 Forbus St., Poughkeepsie, N.Y.
Schlub, Carl F. (J'38) (BL), Jr. Mech. (Project) Engr., Army Air Forces, Wright Field, Dayton; *for mail,* Route 2, South Charleston, Ohio.
Schluderberg, Christian C. ('22; '35) (KLS), Mech. Engr., U.S. Indus. Chemicals Inc., 5101 Distillery Ave., Baltimore; *for mail,* 5920 Burgess Ave., Baltimore 14, Md.
Schluderberg, Donald C. (J'39) (FKS), 63-50 Wetherale St., Rego Park, L.I., N.Y.
Schmall, Henry Herman (J'42) (ZSLEHF), Serv. Engr., Bailey Meter Co., 424 Sharon Bldg., San Francisco 5, Calif.
Schmarje, Clarence F. (J'33) (NCJM), Partner, Schmarje Tool & Engrg. Co., Muscatine, Iowa.
Schmeisser, Ernest G. ('17), 3333 N. Charles St., Baltimore, Md.
Schmeisser, Wilbur J. (J'35) (JY), Engr., Belden Mfg. Co.; *for mail,* 1301 W. Main St., Richmond, Ind.
Schmelz, Willard F. (J'37), Design Engr., Ward Leonard Elec. Co., 31 South St., Mt. Vernon; *for mail,* 2527 Valentine Ave., Bronx 58, N.Y.
Schmid, Alfred W. ('30), Tool Engr., Robbins & Myers, Inc.; *for mail,* 2141 Harshman Blvd., Springfield, Ohio.
Schmid, Ben Jacob (J'39) (SHNKBE), Mech. Engr., Buffalo Niagara Elec. Corp., 300 Elec. Bldg., Buffalo 3; *for mail,* 79 Orchard Dr., Kenmore 17, N.Y.
Schmid, Carl G. ('43) (CMNO), Ch. Engr., Maint. & Prod. Engrg. Dept., Naval Ord. Plant, 21st & Arlington Ave., Indianapolis; *for mail,* 1431 Pleasant St., Indianapolis 3, Ind.
Schmid, W. E. ('36), 11 rue de Beaumont, Geneva, Switzerland.
Schmid, William Andrew (J'26), V.P., City Ice & Fuel Co., 500—5th Ave., New York 18, N.Y.
Schmidlin, Albertus E. (J'39) (BKSAFZ), Devel. Engr., Walter Kidde & Co., Inc., 675 Main St., Belleville 9; *for mail,* 7-R Prospect St., Caldwell, N.J.
Schmidt, Albert Gottfried ('21) (DO), Rep., Harnischfeger Corp., 4439 Santa Fe Ave., Los Angeles 11, Calif.
Schmidt, Alfred Carl (J'45) (LMCDH), 325 White Oak Lane, Winnetka, Ill.
Schmidt, Alfred Otto ('44) (BCMN), Research Engr., Charge Metal Cutting, Kearney & Trecker Corp., National Ave., Milwaukee 14, Wis.
Schmidt, Arthur A. ('14; '21) (CBN), Cons. Engr., West. Precipitation Corp., 1016 W. 9th St., Los Angeles 15; *for mail,* 2201 Hill Dr., Los Angeles 41, Calif.
Schmidt, Chester William (J'41), Exec. Student, Internatl. Harvester Co., Beuter & Pontiac St., Ft. Wayne; *for mail,* 507 E. Faber St., Ft. Wayne 5, Ind.
Schmidt, Elmer F. E. ('19; '29) (CEFKSY), V.P., Lone Star Gas Co., 301 S. Harwood, Dallas 1, Tex.
Schmidt, Eugene Arthur (J'25) (CMLDSW), Asst. Indus. Engr. Officer, Norfolk Naval Shipyard; *for mail,* 102 Smith Ave., Portsmouth, Va.
Schmidt, Fredk. J. (J'36), 1508 Park Ave., Ft. Wayne, Ind.
Schmidt, Fredrick William ('35; '43) (BNEMJ), Sr. Engr., Charge of Engrg. Dept., Wyrstapes Co., 200 Hudson St., New York 13; *for mail,* 257 Linden St., Brooklyn 27, N.Y.
Schmidt, George Gerald ('13; '16; '35) (EFKLOS), Sr. Partner, Connolly & Schmidt, 10 W. 37th St., New York 18, N.Y.
Schmidt, Harold August (J'41) (SOLKJ), Asst. Field Engr., Commonwealth Edison Co., Chicago; *for mail,* 6111 Nassau Ave., Chicago 31, Ill.
Schmidt, Harry ('38) (ABFJKS), Contract Engr., Carrier Corp., 405 Lexington Ave., New York 17, N.Y.; *for mail,* 130 Westville Ave., Caldwell, N.J.
Schmidt, Harry Paul ('30; '38) (BZAHNK), Prof. & Head, Dept. of Engrg., Hillyer Jr. College, Pearl & Jewell Sts., Hartford, Conn.
Schmidt, Jack Frank (J'45) (KBHJCF), Student Engr., Carrier Corp., 300 S. Geddes St., Syracuse 1, N.Y.; *for mail,* 5917 S. Emerald Ave., Chicago 21, Ill.
Schmidt, John H. ('30; '36) (CJBDLM), Asst. to Ch. Engr., Natl. Tube Co., 1714 Frick Bldg., Pittsburgh 30, Pa.
Schmidt, Knute M. ('33; '39) (TLCZ), Research Engr., N. Am. Rayon Corp., Elizabethton, Tenn.
Schmidt, Ralph ('45), Ch. Mech. Engr., Canadian Loco. Co., Ltd., Kingston, Ont., Can.
Schmidt, Richard B. (J'37), Cons. Engr., Zephyr Hill, Springfield, Ohio.
Schmidt, Roger Wilbur (J'45) (CLZ), Engr., Norden Labs. Corp., 34 Varick St., New York, N.Y.; *for mail,* 539 Grove St., Ridgewood, N.J.
Schmidt, Roy H. (J'41) (HKS), Cpl., Army Air Forces, A.P.O. 12744, c/o Postmaster, San Francisco, Calif.
Schmidt, Warren ('45) (CJMLYD), Pres., Mgr., City Plating Works, Inc., 66 Pine St., Bridgeport 5; *for mail,* 3 Rocky Ridge Dr., Bridgeport 18, Conn.
Schmidt, Warren E. (J'43) (EFM), 17565 San Juan Dr., Detroit, Mich.
Schmidtchen, Robert Paul ('28) (MZYJH), Mech. Designer, Sperry Gyroscope Co., Stewart Ave. & Clinton Rd., Garden City; *for mail,* 37 Sylvan Pl., Valley Stream, N.Y.
Schmitt, Bernard A. ('36) (AMB), 3218 W. Polk St., Chicago, Ill.
Schmitt, George H., Jr. (J'40), Measurement Engr., New Orleans Pub. Serv. Inc., 317 Baronne St.; *for mail,* 4939 S. Galvez St., New Orleans, La.
Schmitt, William Charles (J'44) (JCOMG), Mech. Engr., Flesch & Schmitt, Inc., 118 Brown St., Rochester 6; *for mail,* 590 Beach Ave., Rochester 12, N.Y.
Schmitz, Carl Edward ('45) (HMY), Ch. Engr., Crane Packing Co., 1800 Cuyler Ave.; *for mail,* 1455 Cuyler Ave., Chicago 13, Ill.
Schmock, Carl John (J'42) (BKMNYC), Design Engr., Gen. Elec. Co., 2901 E. Lake Rd., Erie 2; *for mail,* 854 Priestly Ave., Erie, Pa.
Schmoyer, Richard L. (J'37) (BLHN), Mech. Engr., Aldrich Pump Co., 5 Pine St.; *for mail,* 1560 Liberator Ave., Allentown, Pa.
Schmudde, Albert August (J'42) (EA), Exper. Engr., Army Air Forces, Wright Field, Dayton, Ohio; *for mail,* Chamois, Mo.
Schnabel, Julius William (J'43) (ABJKO), Design Engr., Columbia Aircraft Corp.; *for mail,* 88 E. Valley Stream Blvd., Valley Stream, L.I., N.Y.
Schnacke, Richard N. (J'41), Mech. Engr., Aluminum Co. of Am.; *for mail,* 132 Beach St., Massena, N.Y.
Schnackel, Harold Clement (J'43) (SEK), 211 Stiles St., Elizabeth 3, N.J.
Schnaible, Albert Paul (J'41) (AMNHF), Engr., Products Div., Bendix Aviation Corp., South Bend; *for mail,* 1113 Prospect Dr., Mishawaka, Ind.
Schneck, Curtis Elias (J'42) (ABNJ), Aircraft Stress Analyst, G & A Aircraft, Inc., Pitcairn Field, Willow Grove; *for mail,* 1102 Pennypack Circle, Hatboro, Pa.
Schneider, Arthur John Rudolph (J'45) (ABO), Calif. Inst. of Tech., 1201 E. California St., Pasadena; *for mail,* 825 E. Del Mar St., Pasadena 5, Calif.
Schneider, Bernard Robert ('27) (BGHLNT), Ch. Tool Engr., Columbia Mch. Works Inc., 255 Chestnut St., Brooklyn, N.Y.; *for mail,* 621—6th Ave., Lyndhurst, N.J.

Schneider, Carl Albert ('26) (CEFMOS), Sr. Engr., Charge of Engrg. Dept., N.Y. Office, Ford, Bacon & Davis, Inc., 39 Broadway, New York 6, N.Y.
Schneider, Fred (J'46) (CMY), 69-81—108th St., Forest Hills, N.Y.
Schneider, Fred B. (J'39) (KRB), Design Engr., Loco. Div., Gen. Elec. Co., 2901 E. Lake Rd., Erie; *for mail,* 3005 Woodlawn Ave., Wesleyville, Pa.
Schneider, George Russell ('41) (HBC), Ch., Engrg. Div., U.S. Engr. Office, 300 Broadway; *for mail,* 711 N. Ash St., Little Rock, Ark.
Schneider, George William (J'42) (KLYSZD), Project Engr., Rohm & Haas Co., Bristol, Pa.; *for mail,* Mercer & Burlington Ave., Ashland, N.J.
Schneider, Gerhart Rudolf (J'44) (CMS), Research Test Engr., Chance Vought Aircraft Div., United Aircraft Corp., Stratford; *for mail,* 35 Alenier St., Hamden 14, Conn.
Schneider, Otto ('44) (OSLKNE), Asst. Ch. Engr., Charge of Engrg., Schwarz Labs., Inc., 202 E. 44th St., New York 17; *for mail,* 102-37—65th Rd., Forest Hills, L.I., N.Y.
Schneider, Raymond Milton (J'44) (DLO), Assoc. Editor, Rock Products Publ. Co., 309 W. Jackson Blvd., Chicago 6, Ill.
Schneider, Robert Edward, Jr. (J'44) (NYB JOC), Cpl., Army Air Forces, Draftsman & Remote Control Turret Mechanic, Branch 6, Sqd. A., 1060th Base Unit, Greensboro, N.C.; *for mail,* 221 S. Genois St., New Orleans 19, La.
Schneider, Robert Frederick (J'43) (MCH), Staff Sgt., Signal Corps, 9463rd Tech. Serv. Unit, Radio Propagation Unit, Holabird Sig. Depot, Baltimore, Md.; *for mail,* 3230 Baker St., San Francisco 23, Calif.
Schneider, Rollin L. (J'45) (AKS), Asst. Supt. of Utilities, Univ. of New Mex., Box 136; *for mail,* 415 Hudson Ave., Albuquerque, New Mex.
Schneider, Rudolph George (J'43) (JMTWRA), Ensign, U.S.N.R., Termination Officer, c/o Naval Inspr. of Ord., Westinghouse Elec. Corp., Sharon, Pa.; *for mail,* 6309 Meis Ave., Cincinnati 24, Ohio.
Schneider, Theodore Anton (J'41) (JSKAEL), Instr., Mech. Engrg. Dept., Newark College of Engrg., 367 High St., Newark 2; *for mail,* 239 Chestnut St., Union, N.J.
Schneider, Wm. (J'41) (BJS), Design Engr., Westinghouse Elec. Corp., East Pittsburgh; *for mail,* 2352 McNary Blvd., Wilkinsburg, Pa.
Schneider, William Charles ('30; '35) (CLM), Asst. Supt. Engrg. & Prod., Waterbury Brass Goods Branch, Am. Brass Co., Box 829, 26 Crane St., Waterbury 88; *for mail,* 245 Country Club Rd., Waterbury 83, Conn.
Schneitter, Lee ('21; '25; '35) (EFSJL), Diesel Engr., Ebasco Services Inc., 2 Rector St., New York 6, N.Y.
Schnitman, Armand Roy (J'46), 3640 Harvey Rd., Cleveland Heights, Ohio.
Schnitzer, A. J. (J'37) (P), 84-06—109th St., Richmond Hill 18, N.Y.
Schnitzer, Sidney (J'45) (AHL), Ch. Engr., Indus. Visualization Associates, 826 S. Flower St., Los Angeles 14, Calif.

Wasser, Reuben ('28; '34; '35) (BFS), Mech. Engr., Pub. Serv. Elec. & Gas Co. of N.J., 396 Clinton Ave.; *for mail*, 50 Elmwood Ave., Irvington, N.J.

Wasserlauf, Bernard Charles (J'43), Master Sgt., Trans. Corps, U.S.A., 1111th Port Mar. Maint. Co., A.P.O. 75, San Francisco, Calif.; *for mail*, 238 Wainwright St., Newark 8, N.J.

Wasson, John W. (J'25) (CESLFD), Mgr., Engr. & Mchy. Sales Div., Von Hamm-Young Co. Ltd., Box 2630, Honolulu 3, T.H.

Waterbury, Lewis Clement ('24) (RMC), V.P., Mgr., Ponce & Guayama R.R., Cent. Aguirre Associates, Guayama, P.R.

Waterfall, Harry William ('21) (NSKF), Prof., Head, Mech. Engrg. Dept., La. State Univ., Baton Rouge 3, La.

Waterman Edwin S. (CESFO), Dist. Mgr., Busch-Sulzer Bros.-Diesel Eng. Co., 3300 S. 2nd St., St. Louis 18; *for mail*, 3935 Fillmore St., St. Louis 16, Mo.

Waterous, Charles Alexander ('16), Retired; 69 Dufferin Ave., Brantford, Ont., Can.

Waters, Daniel Vaughn ('17; '21; '27) (MBJLO), Mech. Engr., West. Elec. Co., Inc., 100 Central Ave., Kearny; *for mail*, "Wa-Rid," R.F.D. 2, Flemington, N.J.

Waters, Everett O. ('14; '25; '35) (BNAHR), Prof. Mech. Engrg., Yale Univ., 15 Prospect St., New Haven 11, Conn.

Waters, Vincent Frederick ('44) (BDGLMW), Gen. Mgr., Ernest H. Abernethy Publ. Co., Inc., 75—3rd St., N.W., Atlanta, Ga.

Waters, William Laurence ('09) (ORCSMN), Partner, Bury & Waters, 150 Nassau St., New York 7; *for mail*, 83 N. Broadway, White Plains, N.Y.

Watkins, Arold ('45) (SCDFL), Draftsman, Kodak Park Works, Eastman Kodak Co., Rochester 4; *for mail*, 96 Mayfair Dr., Rochester 5, N.Y.

Watkins, Charles Albert (J'39) (MND), Engrg. Draftsman, Pangborn Corp., Pangborn Blvd.; *for mail*, 840 Mulberry Ave., Hagerstown, Md.

Watkinson, Roland Martin ('35; '43) (CSE), Estimator, Fed. Shipbldg. & Dry Dock Co., 744 Broad St., Newark, N.J.; *for mail*, 796 E. 37th St., Brooklyn 10, N.Y.

Watlington, E. Hugh ('31), Dept. Mgr., Pearman Watlington & Co., Hamilton, Bermuda, B.W.I.

Watson, Bruce Bastress ('44) (RFKJS), Res. Inspr., Test Dept., Pa. R.R.; *for mail*, 1300—20th Ave., Altoona, Pa.

Watson, David Milnes (J'45) (SKOEFC), Engrg. Design Dept., Wickes Boiler Co.; *for mail*, 1320 Owen St., Saginaw, Mich.

Watson, Douglas (J'43) (CMJD), Asst. to Ch. Indus. Engr., Columbia Steel Co., 235 Montgomery St., San Francisco 6; *for mail*, 37 Northampton Dr., Palo Alto, Calif.

Watson, Fred Burton (J'45), Westinghouse Elec. Corp.; *for mail*, Box 2, Paul, Idaho.

Watson, Harold Fielding ('43) (DBJ), Stands. Engr., Link-Belt Co., 2045 Hunting Park Ave., Philadelphia; *for mail*, 519 E. Tulpehocken St., Philadelphia 44, Pa.

Watson, Harold H. ('28) (CMS), Mgr., Elec. Operas., No. States Power Co., 15 S. 5th St., Minneapolis 2, Minn.

Watson, Harry Dexter ('38) (SEFAW), Prof., Head, Mech. Engrg. Dept., Univ. of Me., Orono, Me.

Watson, Henry Daniel ('35) (KSCDBL), Ch Tech. Engr., Mitchell Engrg. Ltd., Bedford Sq., London, W.C.1; *for mail*, 68 Bullhead Rd., Boreham Wood, Herts, England.

Watson, Herbert Lockridge ('07; '21) (CSJMNR), Pres., De Laval Steam Turbine Co., Trenton 2; *for mail*, 27 Whittier Ave., Trenton 8, N.J.

Watson, Max Powell ('39; '45) (EFMOY), Dist. Engr., United Gas Pipe Line Co. & Union Producing Co., Box 1628, New Orleans 11, La.

Watson, Ralph M. ('40; '44) (BNCHSE), Asst. to V.P. in Charge of Engrg., Worthington Pump & Mchy. Corp., 401 Worthington Ave., Harrison; *for mail*, 23 Hazelwood Rd., Bloomfield, N.J.

Watson, Raymond H. ('28; '34; '35) (BDJHSZ), Mech. Engr., U.S. Engr. Office, 10 E. 17th St., Kansas City 8; *for mail*, 5011 Park St., Kansas City 4, Mo.

Watson, Robert ('43) (RYFABZ), V.P., Waugh Equip. Co., 310 S. Michigan Ave., Chicago 4, Ill.

Watson, Robert Fulton (J'44), 1111 Union St., Alameda, Calif.

Watson, William ('20), Retired; 1464 S. 76th St., West Allis, Wis.

Watson, William Freeborn (J'37) (CMLYJ), 63 Longfellow, Detroit 2, Mich.

Watson, William Malcolm (J'41) (BCM), Mech. Engr., Charge Design, Hygrade Sylvania Corp., Danvers; *for mail*, Salem Country Club, Peabody, Mass.

Watt, John Reid (J'36) (MAEYO), Instr. in Mech. Engrg., Univ. of Tex., Austin; *for mail*, 1011 W. 31st St., Austin 21, Tex.

Watters, Ray Bradshaw, Jr. (J'43) (CLM), Aviation Electronics Technician, U.S.N., Box 15-17, Akron; *for mail*, 1328 Delia Ave., Akron 2, Ohio.

Watters, S. Edmund (J'42) (NJRLBS), Mem. Tech. Staff, Bell Tel. Labs., Inc., 463 West St., New York 14, N.Y.

Watts, George W. ('24; '35) (LBKJZS), Dir. Engrg., Stand. Oil Co. of Ind., 910 S. Michigan Ave., Chicago 80, Ill.

Watts, Robert Lucien ('18) (CELMOS), Mgr., Lubriplate Div., Fiske Bros. Refining Co., 129 Lockwood St., Newark 5, N.J.; *for mail*, 25 Central Park W., New York 23, N.Y.

Wauchope, George Andrew ('44) (HBNSZ), Dir., Gwynnes Pumps Ltd., Hammersmith, London, W. 6; *for mail*, 24 Hertford Ave., East Sheen, London, S.W. 14, England.

Waugaman, Arthur Rankin ('46), Dist. Mgr., Babcock & Wilcox Co., 1525 Ford Bldg., Detroit; *for mail*, 253 Merriweather Rd., Grosse Pointe Farms, Mich.

Way, David Spencer (J'44) (ASZK), Test Engr., Wright Aero. Corp., Paterson 3; *for mail*, 21 N. 13th St., Haledon, Paterson 2, N.J.

Way, Stewart (J'39) (BEAFSJ), Sec. Engr., Thermodynamics Research Labs., Westinghouse Elec. Corp., East Pittsburgh, Pa.

Wayman, Robert William (J'40) (CHNMAJ), Project Engr., Detroit Transmission Div., Gen. Motors Corp., 5140 Riopelle St., Detroit 11; *for mail*, 21650 Moross Rd., Detroit 24, Mich.

Waymouth, Geo. W. ('39), R.F.D. 10, Loudon Branch, Concord, N.H.

Wean, Raymond John ('28) (JBCLMY), Pres., Wean Engrg. Co., Inc., 347 N. Park Ave., Warren, Ohio.

Weatherhead, Charles Frank (J'43), 274 St. Clarens Ave., Toronto, Ont., Can.

Weatherly, Richard M. (J'44) (EAH), Route 4, Greensboro, N.C.

Weaver, Clarence Roberts (J'40) (RCDFS), Gang Foreman, Meadows Enginehouse, Pa. R.R. Co., Kearny, N.J.; *for mail*, 15 N. 2nd St., Sunbury, Pa.

Weaver, Earl Lewis, Jr. (J'43), Student Engr., Natl. Tube Co.; *for mail*, 225 Oxford Dr., McKeesport, Pa.

Weaver, Earl Marshall (J'39) (JMCB), Ch. Engr., Gray Tool Co., Box 1655, Houston 1, Tex.

Weaver, Edgar L. (J'42) (SRBH), 1809 Berkley Ave., S.W., Grand Rapids 9, Mich.

Weaver, Ernest Witwer ('20; '26) (FNKJCB), Asst. Ch. Engr., Surface Combustion Corp., Toledo 1; *for mail*, 1622 Potomac Dr., Toledo 7, Ohio.

Weaver, Frank Roderick ('23) (CJTWM), Pres., Hibben, Hollweg & Co., 110 S. Meridian St., V.P., E. C. Atkins & Co., 402 S. Illinois St.; *for mail*, 110 S. Meridian St., Indianapolis, Ind.

Weaver, James R. ('36) (CDM), Plant Mgr., Westinghouse Elec. Corp., 653 Page Blvd., Springfield 2, Mass.

Weaver, Leon H. A. ('21; '25) (CSL), 423 Birch Pl., Westfield, N.J.

Weaver, Richard Durbin (J'40) (NBMJAO), Mech. Engr., Hallicrafter Co., 2611 Indiana Ave., Chicago 11; *for mail*, 5741 Kenmore Ave., Chicago, Ill.

Weaver, William Edward (J'34) (YWKJA), Lt. Comdr., Bur. of Aero., Navy Dept.; *for mail*, 3207 Foxhall Rd., N.W., Washington, D.C.

Weaver, William Henry ('27; '32 '35) (CMDO), Ch. Indus. Engr., Crown Can Co., Erie Ave. & I St., Philadelphia 34; *for mail*, 326 Derwyn Rd., Lansdowne, Pa.

Webb, Albert Erickson (J'39) (HNBCZ), Mech. Engr., Stewart-Warner Corp., 1826 Diversey Pkwy., Chicago 14; *for mail*, 3757 N. Fremont St., Chicago 13, Ill.

Webb, Baxter Hill (J'36) (CADRBE), Assoc. Automotive Engr., Dept. of Street Rys., City of Detroit, 14129—2nd Blvd., Highland Park 3; *for mail*, 14912 Rosemary, Detroit 5, Mich.

Webb, Benjamin Wellington ('40) (CFS), Philadelphia Dist. Mgr., Combustion Engrg. Co., Inc., 1616 Walnut St., Philadelphia, Pa.

Webb, Charles Carrick ('41) (NBYDMZ), Mech. Engr., Mchy. Devel. Gp., Engrg. Dept., E. I. du Pont de Nemours & Co.; *for mail*, 1303 Rodney St., Wilmington, Del.

Webb, Clifford L. (M'43), Creamery Package Mfg. Co., 692 Ponce de Leon Ave., Atlanta, Ga.

Webb, Ernest Clarence ('44) (FKS), Engrg. Serv. Mgr., Iron Fireman Mfg. Co., 3170 W. 106th St., Cleveland; *for mail*, 24721 West Lake Rd., Bay Village, Ohio.

Webb, Frank Kline, Jr. (J'39) (ALC), Maj., 410-7 Kearny, Ft. Leavenworth, Kan.

Webb, George Henry (J'44) (D), Asst. Ch. Engr., Jervis B. Webb Co., 8951 Alpine Ave., Detroit 4, Mich.

Webb, Jervis Bennett ('27) (CD), Pres., Gen. Mgr., Jervis B. Webb Co., 8951 Alpine Ave., Detroit, Mich.

Webb, Jervis Campbell (J'37) (DMCB), Mech. Engr., Asst. to Presiding Officer, Jervis B. Webb Co., 8951 Alpine Ave., Detroit 4, Mich.

Webb, John Henry Edward (J'46), 163 Earlsdale Ave., Toronto 10, Ont., Can.

Webb, Ralph Duvivier ('42) (ZLSC), Head, Instrument Dept., Carbide & Carbon Chemicals Corp., South Charleston 3, W.Va.

Webb, Robert G. (J'39) (BHK), Lab. Technician, Chrysler Corp., 12800 Oakland Ave., Detroit; *for mail*, 1327 Troy-West, Ferndale, Mich.

Webb, Thomas Clifford (J'38) (BEKM), Sales Engr., Clark Bros. Co., Inc., 5715 Bickett, Huntington Park, Calif.

Webb, Thomas Lake Berry ('44) (OSHKZF), Staff Engr., Utility Consultant, So. Calif. Gas Co. Rubber Reserve, 553 Rameriz St., Los Angeles; *for mail,* 815 Northwood Ave., Compton, Calif.
Webber, Harold S. ('39) (CDGM), Plant Supt., Mech. Engr., Schorsch & Co., 120 Bruckner Blvd., Bronx 54, N.Y.

The Design of Mechanical Auxiliaries for TVA Hydroelectric Plants

By H. J. PETERSEN,[1] KNOXVILLE, TENN.

Sixteen hydroelectric power plants have been designed by the Tennessee Valley Authority during the past ten years. Changes and improvements have been incorporated in each successive design, as a result of experience gained in operation of each plant. This applies particularly to mechanical auxiliaries involved. It is this phase of the design which is treated in the present paper, specific reasons being given for adoption of the particular auxiliaries discussed.

During the past decade the Tennessee Valley Authority has designed sixteen hydroelectric power plants which include almost every type of plant except those using Pelton wheels. These plants were all designed by essentially the same organization, which resulted in a succession of improved designs as experiences gained in the earlier plants were incorporated in the designs of the later plants. This is especially true in the case of the mechanical auxiliaries since considerable latitude is permitted in the design of these systems. Consequently, it has been possible to standardize on a good many features of these auxiliaries which have proved themselves in service.

This paper will discuss the design of the various mechanical auxiliaries for hydroelectric power plants as developed by the Authority, outlining the reasons establishing the designs adopted. It is expected that these designs will be superseded by later and better designs as operating experiences and improved techniques dictate. It is not intended that this paper shall represent a comprehensive treatise on hydroelectric power-plant piping and auxiliaries, as these subjects are well handled in numerous textbooks and manuals; however, the scope of this discussion makes it desirable to complement the specific references to TVA design with a review of certain related principles which the author considers good general piping practice.

In general, the term "mechanical auxiliaries" includes those systems usually consisting of one or more machines connected by piping to the main prime movers to aid them in their proper functioning, or other systems distributed throughout the powerhouse for services such as water, air, drainage, and so forth. Because they occupy relatively small spaces and usually are located in out-of-the-way places in the powerhouse, these systems sometimes do not receive their full share of attention and may be slighted in the design. In almost all cases they are vital to successful and economical operation, and thought given to their design in the preliminary stages will pay dividends in the long run in the trouble-free operation of the plant.

However, the amount of time and effort spent in the design of these features should be justified by the results required. Elaborate calculations and long and complicated empirical and theoretical formulas should be resorted to only when the results prescribed make their use unavoidable. Only a novice will carry out a computation to two or three decimals when a lesser number of significant figures will suffice. An experienced designer is aware of this and has available a number of charts, tables, and curves, from which he is able to pick certain approximate values which facilitate his design. Also, a practical designer will always maintain a close liaison with the department that will operate the plant in order to ascertain its likes and dislikes in the matter of machinery and equipment. Many times that department, because of its operating experiences, can make worth-while contributions to the design.

General Considerations

Before reviewing the design of the individual systems, several features common to all systems and on which generalizations may be made will be discussed.

Piping. The fundamental requirement for any piping system is that it shall be functionally correct. All valves and items of equipment should be in proper relation to each other, so that the system operates in the most efficient manner possible.

The best way to obtain this result is by making a valve-operation diagram. Fig. 1 is such a diagram for a governor and lubricating-oil system at one of the Authority's plants. It will be noted that this diagram outlines the entire system, including all valves, equipment, and machinery. From this it is an easy matter to check the over-all design of the system from a functional standpoint. This diagram, made in sketch form before any drawings are begun, serves as a guide to the draftsman in making the detailed drawings. When made into a final drawing, it has the further purpose of aiding the field erection forces in the installation of the piping, and finally it enables the operators to visualize the system as a unit which promotes more efficient operation. Each valve on each system is marked with an aluminum tag describing its function (see Fig. 2). Tags A, B, and C are attached to the valve handwheels underneath the nut, while tag D is attached to the valve-bonnet bolt, to the valve stem, or to the operating chain. Each valve is numbered according to a standard system, and an experienced operator can tell the relative location of a valve in the piping system by its number. The symbols shown on this drawing for the various kinds of valves and items of equipment are standard for the diagrams for all plants.

During the preliminary stages of the design of the powerhouse, adequate consideration should be given to the physical location of the pipe lines. It is absolutely essential that all the various systems be considered as a group in order to lay out the space requirements properly. Close co-ordination between the piping designer, the architect, and the concrete designer is essential at this stage of the design in order to insure proper space for pipe galleries, tunnels, and riser shafts.

Fig. 3 shows a gallery containing a number of piping systems. It will be noted that the gallery is of ample size, that all the pipes are racked along the wall parallel to the building lines, and that they provide adequate headroom. As a contrast, one of the earlier designs showing the piping around the top of a shaft is illustrated in Fig. 4. Note the pipe at angles to building walls, the inaccessibility of valves, some valves upside down, and the general appearance of having been designed one system at a time instead of as a group. The improvement in the oil piping shown

[1] Head Mechanical Engineer, Tennessee Valley Authority. Mem. A.S.M.E.

Contributed by the Hydraulic Division and presented at the Spring Meeting, Chattanooga, Tenn., April 1–3, 1946, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of authors and not of the Society.

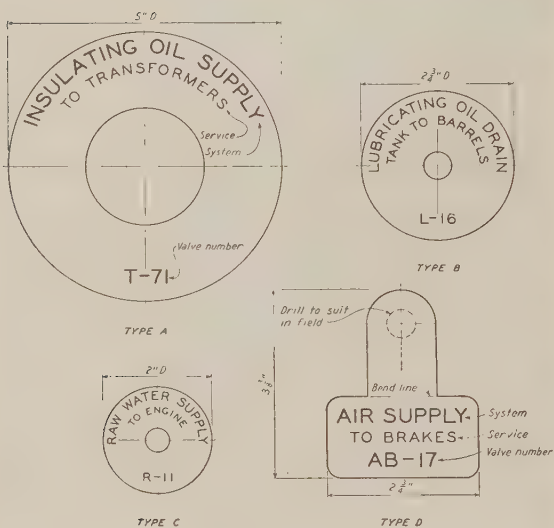

Fig. 2 Valve Marker Tag

Fig 3. Piping in Gallery

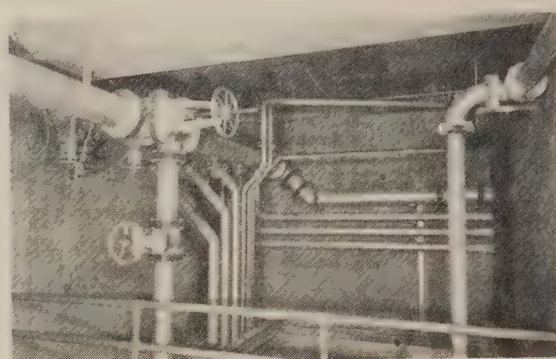

Fig. 4 Piping at Top of Shaft

in Fig. 6, over that shown in Fig. 5, is evident. Fig. 5 has large radii bends combined with welding fittings, pipes crossing each other at angles, pipe in more than one plane, and a multiplicity of valves and piping.

By locating the equipment closer to the walls and by using three-way cocks, as shown in Fig. 6 for a similar system in a later powerhouse, it was possible to eliminate many valves and some of the piping. The use of welding fittings throughout and the uniform spacing of the headers result in a piping design which places the accent on simplicity and good appearance as well as

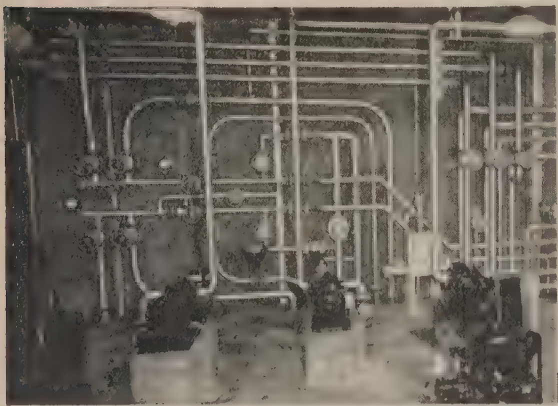

Fig. 5 Piping in Oil-Purification Room in One of Earlier Plants

Fig. 6 Piping in Oil-Purification Room in Later Plant

functionalism. The choice of the operator between these two designs is obvious.

The greatest part of the steel pipe used by the Authority for hydroelectric plants is purchased under A.S.T.M. Specification A 120, standard weight (ASA-B36.10). For certain pipe assemblies where considerable bending or coiling of the pipe is necessary, the pipe is specified as A.S.T.M.-A53, Grade A. Wrought-iron pipe is purchased under A.S.T.M. Specification A72. All cast-iron pipe is bell and spigot centrifugally cast, with class depending upon the pressure. Cast-iron pipe for pressure lines is purchased cement-lined, as it may be had at little or no increase in price, and experience has proved that it is much more resistant to tuberculation. Cast-iron pipe is purchased in 16- or 18-ft lengths, depending upon the supplier. Shorter lengths are seldom used because of the added calking expense.

In some of the larger-size mains, it has proved advantageous to use spiral-welded pipe. This is especially true in drainage lines embedded in concrete where the cost of steel or cast-iron pipe would not be justified. Steel pipe is purchased in random lengths with ends threaded and coupled, or beveled for welding, as the case may be. We find that it is cheaper to weld pipes 4 in. and larger than to use screwed flanges. It also saves time and expense to have complicated welding pipe assemblies shop-welded into subassemblies which are then welded together in the field.

The Authority makes single-line detailed construction drawings for piping systems using pipe 2 in. and smaller and for large-scale yard piping of all sizes. They can be made much faster and, except in some congested areas, they give a satisfactory physical picture. Any congested areas are developed either with standard double-line drawings or by isometric projection. Duplication of views, notations, dimensions, and mark numbers are avoided as they add to the design expense and increase the chances for error.

Where lines lead directly to headwater or tail water, heavier construction is used up to the first valve to guard against possible breakage. A special connection is used where embedded lines emerge from the concrete in the various galleries. In smaller lines a screwed coupling is placed flush with the face of the concrete wall; this permits ready replacement in case of breakage in the line. In larger steel lines a standard cast-iron sleeve is placed flush with the concrete wall, and the exposed pipe is calked therein. Cast-iron lines emerging from concrete are placed with the end of a bell flush with the face of the wall.

Pipes passing through walls and floors are sleeved, with sleeves in floors extending 1 in. above the floor to permit floor washing without water spilling to the room below. Black steel pipe is used for sleeves, except where rust action would prove objectionable, in which case galvanized sleeves are used. Piping systems are provided with drains at the low points to facilitate repairs and to drain water lines which are subject to freezing. A good designer always provides a closure piece in a piping system between two pieces of equipment where there are intervening flanged fittings or valves, instead of designing the system fitting to fitting. This is necessary because fittings and valves seldom are furnished to exact dimensions, and the closure piece takes up the inaccuracies in dimensions. Pipe lines are arranged to provide adequate access to machinery for inspection and repair, and to permit the removal of equipment without the necessity of dismantling large sections of piping. Fig. 6 is a good example of this.

It is of prime importance in the design of a piping system to provide for the maximum ultimate requirements. This is especially true in trunk lines for water-supply mains and plumbing waste lines. Our experience has been that as a project develops, more and more demand is placed upon these two systems. A liberal estimate of ultimate requirements is the best insurance against insufficient capacity in the future.

Next in importance to functionalism in a piping system is that the design shall be economical. This factor involves the proper selection of the material, type, and size of the various pipe, valves, and equipment. It is compounded from a great many elements, some of the more important of which are (1) expected life versus cost, (2) higher pumping costs because of reduced sizes versus smaller initial investment, and (3) increased operating conveniences and reduced maintenance expense versus the added cost for obtaining these features. If these three points are carefully evaluated in the design of each system, it is fairly certain that an economical design will result.

From past experience and from technical data on the subject, the expected life of a pipe or valve may be closely estimated. Obviously, the longer life is more desirable, but it is necessary for the designer to balance the extra years of service against the added cost necessary to obtain it.

The size of each pipe line, once the maximum flow is established, is almost entirely a function of the pressure drop due to friction in the line. It is necessary to investigate each line for head loss, using the friction characteristics for the fluid carried. Sizes of equipment connections should never be construed as indicative of proper pipe size. In most cases the size of pipe mains for water systems is dictated by the flow necessary for fire protection. In evaluating pumping costs and pipe sizes, it must be remembered that station power is cheap in a hydro plant. On the other hand, most of the added cost of a larger-size pipe is the material itself, since the labor of installing each-size line is practically the same. It is advisable not to have too many different

sizes and kinds of pipe in a plant since this requires a larger stock of replacement parts for valves and specialties.

The amount of money that should be spent for operating conveniences and reduced maintenance is largely determined by experience and judgment. A good many operating conveniences may be had without extra cost if the systems are properly designed. Valves should be located so that their purpose is apparent at a glance, and they should be accessible, especially those required in an emergency, using chain wheels where necessary. There should be sufficient unions in screwed lines to facilitate disassembly. All waste and drain lines, especially those buried in concrete, should have cleanouts at strategic points. The practice of burying plumbing or other piping in walls should be avoided; it is much better to provide access corridors behind the fixtures for service and maintenance.

Valves. The function of a valve in a piping system is either to regulate the flow of the fluid in the line or to sectionalize a piece of equipment or part of the system. Globe valves are used for the first function and gate valves for the second. Since most of the valves in hydro plants require only infrequent operation and are seldom used for throttling service, gate valves are used in the majority of cases. Globe valves are used on by-passes around special valves and regulators with a gate valve on either side of the equipment by-passed.

The Authority prefers a rising-stem valve to a nonrising-stem valve because the position of the stem indicates the position of the disk and because the stem threads are not in contact with the fluid. The O.S.&Y. type of rising-stem valve has the further advantage that the stem threads are outside the valve when open, making it possible to examine and lubricate them with the valve in service. The additional headroom which is required for the rising-stem valve over a nonrising-stem valve is of small importance.

Globe valves usually are purchased with plug-type disks because that type of disk gives excellent throttling service, has great resistance to wear, and is easily repaired. The so-called composition disk has not proved as satisfactory for throttling and wears out quickly. Gate valves 2 in. and larger usually are purchased with double disks, and smaller than 2 in. with wedge disks. A double-disk valve gives a tighter shutoff and is more easily repaired in the field. Sometimes a larger-size wedge-disk valve is used when it is impossible to install the valve with the stem up. In this position the disk of the double-disk valve is liable to jam. Gate valves smaller than 2 in. are purchased with wedge disks because, in our opinion, the various parts in a double-disk valve in those sizes are too small.

Valves 2 in. and smaller, both gate and globe, usually are purchased all brass because the extra cost involved is nominal. Larger valves are purchased iron body, bronze-mounted. The use of cleanouts in valve bodies has not been found necessary, nor has it been necessary to specify air-tested valves. Pressures encountered in hydroelectric plants seldom call for by-passes around valves, although at times it has been necessary to provide gearing for the larger-size valves. This, of course, is a function of the pressure on the valve and is investigated for each condition. Larger valves which require fast operation, or are remotely controlled, are fitted with motor operators.

Check valves are used on the discharge of pumps and at all other places where it is imperative to prevent backflow of the fluid. Swing-check valves are preferred, but in some cases lift-check valves are used, especially for upward flow. A balanced-disk or spring-loaded check valve is used to prevent slamming and excessive surges in the higher-head lines.

Bolts and Gaskets. Flange bolts are purchased under A.S.T.M. Specification A 107, with regular unfinished square heads and heavy unfinished hexagon nuts. In rare cases where the bolts are inaccessible and subject to excessive corrosion, such as for fastening inlet gratings to the upstream face of a dam, stainless-steel bolts are used. The thinnest possible gasket consistent with the roughness of the flange, is used, with no gaskets over $^1/_{16}$ in. Ring gaskets are used in preference to full-face gaskets as they make a tighter joint.

Hangers, Supports, and Expansion Joints. In a well-designed piping system the weight of the pipe and its contents are always supported so that no stresses are transmitted to any of the valves or machinery. The stresses introduced in equipment in this manner, coupled with vibration, may eventually break the casting of a pump or valve. Standard commercial hangers are used where possible, as they are cheaper than designing special hangers for individual applications.

While the temperatures encountered in hydro-plant piping systems do not give rise to many expansion problems, the long lengths of the lines in a multiunit plant do call for some expansion design. The Authority uses pipe bends and offsets, where possible, in preference to guided slip joints with packing boxes. Sometimes, where vibration is coupled with expansion in a pipe line, a corrugated type of joint is used.

Painting. All piping systems of the Authority, including all insulation, are painted for appearance, protection, and identification, in accordance with a standard color code. Each system has its own color, and this standard is maintained throughout all the plants. The whole system is first painted with an aluminum paint, and identification is obtained by painting the periphery of flanges or by painting an occasional screwed elbow or tee, as the case may be, with the color of that particular system. If the length of line between these identification points is long, a narrow band is painted around the pipe at intervals. Arrows are sometimes painted on pipe lines where the direction of flow is not evident at a glance.

Control Valves. Control valves are used by the Authority in hydro plants for pressure regulating, temperature regulating, pressure relief, and maintaining liquid level. Pressure-regulating valves are used for reducing the water pressure to generator air and oil coolers, turbine oil coolers and runner seals, air-conditioning equipment, air-compressor jackets and aftercoolers, and general plant services. Where the pressure drop is low direct-operated spring-loaded diaphragm valves are installed, while pilot-operated valves are used for high-pressure drop. The pilot-operated valves are of the hydraulic or pneumatic type. The pneumatic type has proved more satisfactory for use on raw river water, as trouble has been experienced with the hydraulic type owing to fouling of the pilot valves, necessitating the installation of strainers in the pilot lines. We have found that filters installed in the air lines ahead of pneumatic valves are a good investment. Small valves and valves used for dead-end service are single-seated, while large valves are double-seated. A pressure gage is always installed on either side of a reducing station.

The sizing of pressure-regulating valves for hydro plants presents a problem because of varying headwater elevations. Since the valves must pass the required amount of water under any head condition, a valve large enough under low headwater may be too large under maximum headwater levels. Likewise a regulating valve on plant service sometimes must also be used for fire protection. This means that water requirements must be estimated very closely, and valves must be selected which have characteristics best suited for their particular service.

Two types of temperature-regulating valves are used, i.e., solenoid and motor-operated from a thermostatic element. Solenoid valves are used on air-compressor jackets and similar services to control cooling water so as to prevent flow and condensation when the service is intermittent. Motor-operated valves, actuated from thermostatic elements, are used on air-

conditioning equipment and to control the cooling water to generator air coolers in remotely controlled plants.

Both spring-loaded hydraulic relief valves and diaphragm back-pressure valves have been used after pressure-regulating valves. Spring-loaded hydraulic relief valves are used in the small sizes and where the comparatively wide relief range is not objectionable. Diaphragm back-pressure valves have proved more satisfactory for large sizes and where close control is required. Relief valves are sized to pass the total amount of water which the pressure-regulating valve will pass under highest head conditions.

Level controls are used in open tanks and station drainage sumps, and for depressing tail water in the draft tube when units are motored. The types used are: the ordinary balanced float valve to maintain a constant level in an open tank from a pressure main, float-operated mercury switches and cam-type float switches to start and stop pumps, and diaphragm valves actuated by float-operated pilots and compressed air to depress tail water in the draft tube when units are motored for condenser operation.

Motors. All machinery in the hydro plants of the Authority is driven by electric motors because of the availability of a reliable power supply and because of the dependability of the modern motor and its simplicity of control.

Motors driving station auxiliaries are general-purpose, N.E.M.A. standard, with class A insulation. Motors driving constant-speed equipment, such as pumps, compressors, and ventilating fans, are squirrel-cage induction type with normal torque and starting current; those for variable speed and torque, such as cranes and hoists, are wound-rotor slip-ring type. Integral-horsepower-size motors are rated 440 volts, 3 phase, 60 cycles. No auxiliaries require motors large enough to make voltages above 440 economical. Fractional-horsepower sizes are 110 or 220 volt single phase. A few auxiliaries, such as emergency turbine guide-bearing, lubricating-oil pumps, and important valves, are provided with 250-volt d-c motors operated from the station service batteries.

Motors in locations where windings might become damaged by water or oil are provided with moistureproof insulation and splashproof or dripproof frames; others have open frames. In very damp locations it has been found necessary to apply strip-type heaters or to circulate a small amount of current through the motor coils to avoid sweating while the motors are shut down.

Controls are centralized on auxiliary-power switchboards for groups of related equipment. Each motor circuit contains a manually operated disconnecting switch, a set of fuses as protection against short circuit, and a magnetic contactor for full-voltage starting and thermal overload protection. Push-button stations for manual control generally are located at or near the motors. Motors under automatic control also have a push button which provides manual control for inspection. Power supply is sufficiently duplicated to assure continuous operation of auxiliaries during usual maintenance and under any reasonable fault conditions.

Individual Systems

Compressed Air. Compressed air is used in the hydro plants of the Authority for operating pneumatic tools, for generator brakes, for pneumatically operated regulating valves, for depressing tail water below the runners for synchronous-condenser operation in those plants where tail water level is normally above the runner, and in one plant (Kentucky) for preventing the formation of ice on the spillway gates.

Pneumatic tools operate most efficiently using air at 80 to 100 psi, and since the other uses for compressed air require pressures of less than this, 100 psi has been adopted as a standard pressure for the compressors. One stationary 105-cfm compressor has been found to have sufficient capacity for all normal plant needs in all plants except Kentucky. This is supplemented by a portable machine of approximately 100-cfm capacity at each plant which is used when major repair work requires additional air capacity.

The Authority has standardized on a horizontal, crosshead type, double-acting, water-cooled, 325-rpm, V-belt-driven, single-stage compressor for the stationary machine. Its low rotative speed and low bearing loads, together with its all-round rugged construction, make it a most dependable machine, capable of giving continuous service over a period of many years with very little maintenance. Dual control is used with these compressors. This control can be set to operate the compressor continuously when there is a steady demand for air, or it can be set to start and stop the compressor automatically when the demand for air is intermittent. The latter control is the one normally used, with the motor being operated by a pressure switch on the receiving tank. All compressors unload to atmosphere to prevent starting the motors under load.

The portable compressor is an air-cooled, single-acting, 2-stage, motor-driven machine complete with intercooler, air receiver, wheeled truck, and all standard accessories. The motor is controlled by a magnetic starter and push-button station mounted on the machine. The compressor is motor-driven because electrical outlets are provided throughout each plant area which make it possible to use the compressor either in isolated locations, such as up on the roadway crossing the dam, or in the powerhouse to supplement the stationary machine.

A water-cooled aftercooler is always used after single-stage compression to remove the excess moisture in the air before it condenses in the distribution system. An "air through the tubes" type of aftercooler with moisture receiver at one end is installed in the discharge piping. The small amount of moisture and oil from the compressor cylinder carried over to the distribution line is removed by traps. These traps are placed at low points in the line for gravity drainage.

An air receiver is placed in the discharge line after the aftercooler to damp the pulsations of the reciprocating compressor and to provide storage of compressed air when the peak demand is greater than the capacity of the compressor. Since the air cools in a receiver, its dew point is lowered and additional condensation takes place, which is removed by a blowoff or a trap. Because air is compressible, the damage resulting from a ruptured receiver is likely to be severe; consequently, the Authority always specifies that the tank shall be fabricated in accordance with the A.S.M.E. Code for Unfired Pressure Vessels.

Certain features of design are observed in the layout of the compressed-air system; some of these are essential and others are desirable. The air intake is connected to outside air whenever possible and fitted with a filter. When this is not feasible, the compressor is located in the lower levels of the substructure where the air is relatively cool and clean. A valve is never placed in the discharge line between compressor and receiver without an intervening safety valve. All air-hose connections are made at the tops of headers to prevent picking up moisture. Cooling water is discharged through an open funnel so that it may be tested for temperature by feeling. The Authority uses black steel uninsulated pipe for air lines. Internal corrosion from condensate has not evidenced itself up to the present time.

The use of air for depressing tail water below the runner[2] and for protection against ice at spillway gates[3] has been fully de-

[2] "Hydraulic Turbine Practice of the TVA," by H. J. Petersen and J. F. Roberts, *Mechanical Engineering*, vol. 65, 1943, pp. 237–244.

scribed in other articles and will be omitted from this paper.

Governor and Lubricating Oil. The Authority uses the same oil for the governor pressure system and for the lubrication of the generator thrust bearing. Some difference of opinion between the governor and generator manufacturers has arisen lately over the viscosity of this oil. The generator manufacturers prefer an oil with a viscosity in excess of 300 S.S.U. at 100 F, while the governor manufacturers prefer this viscosity to be around 250 S.S.U. at 100 F. In order to avoid the necessity of two separate oil systems, oil with a viscosity of 300 S.S.U. at 100 F will be purchased in the future.

We have found that purifying oil by centrifugal force is satisfactory and economical, and we have standardized on that type of machine. A self-contained and enclosed stationary 350-gph unit, complete with centrifuge, motor, pump, electric heaters, temperature control, and all standard accessories, is purchased for each plant. In the early stages of the Tennessee Valley Authority program consideration was given to the use of a portable machine which could be transported to individual plants as required. A central purifying depot, where oil from all plants could be shipped for processing, was also considered. These were both ruled out because of operating inconveniences involved and because the cost of a purifying system is a very small percentage of the total cost of each plant.

Two tanks are provided for each project, one for clean oil and one for dirty oil. Each tank has sufficient storage for the oil in one unit thrust bearing, plus the oil in one governor system, plus a few hundred gallons of extra capacity. When space permits, these tanks are located in the powerhouse adjacent to the oil-purification room. In plants where no space is available the tanks are buried in the fill outside the powerhouse wall. Tanks placed in this manner are designed with an extra $^1/_{16}$ in. of metal to allow for corrosion. In either case the storage tanks are always located so that they may be filled by gravity from the ground level and still provide a positive head on the pumps.

One clean-oil pump and one dirty-oil pump are furnished for each powerhouse. The pumps are standard positive-displacement type with built-in relief valves and are rated 30 gpm when pumping oil at 50 F. A complete piping system is installed at each plant between the units and the purification facilities. The Authority uses black steel, scale-free uninsulated pipe for these oil lines. Experience has proved that it is difficult to prevent leaks in piping using screwed malleable fittings, especially when the oil is hot, as around the centrifuge. Consequently welded joints are used throughout, except at valves and unions, with forged-steel socket welding fittings used for sizes 2 in. and smaller. Oil-resistant gaskets are used when it is necessary to use flanges. No matter how well a pipe line is cleaned, there will always be scale and welding particles carried along in the oil, especially when starting the system. For this reason a filter is installed in the line leading to each unit and a standard Y-type strainer with $^1/_{32}$-in. perforations is used on each pump suction. These filters have 0.005-in. openings through metal slots and are equipped with built-in knife-blade cleaners.

Insulating Oil. Because of its different characteristics from lubricating oil, a separate oil-purification system is installed in each plant for the insulating oil used in the transformers, circuit breakers, and other oil-filled electrical equipment. The same type of machine is used as just described, but because of the larger volumes handled, its capacity is increased to 600 gph. A filter press which raises the purifying capacity to 900 gph is added to this machine to remove the colloidal carbon from the oil.

One clean- and one dirty-oil pump are installed in each plant. They are of the same type as the pumps for the lubricating-oil system, with the capacities increased to 100 gpm each. At some plants it is possible to return the dirty oil from the switchyard to the storage and purification rooms by gravity, and no dirty-oil pump is supplied. One clean-oil tank, one dirty-breaker-oil tank, and two dirty-transformer-oil tanks are provided at each plant. In this way the breaker oil and transformer oil are never mixed after they once have been used. Each of the circuit-breaker-oil tanks (clean and dirty) has storage capacity for one breaker, and the two dirty-oil transformer tanks have a total storage capacity for one transformer.

The same comments apply for the piping as for lubricating oil, except that black wrought iron is used for underground lines in the switchyard. The supply and return lines in the switchyard are not permanently connected to the transformers and breakers; instead, a valve is located in each line near the equipment and a flexible hose is used when filling or draining is necessary. This hose has a specially treated synthetic-rubber lining and is equipped with a flexible ball-joint fitting to facilitate attachment to the service valve. Because the oil is changed at infrequent intervals we find this arrangement entirely satisfactory.

Runner-Hub Oil. In the main river plants which have Kaplan turbines the runner hub is filled with a heavy oil for lubricating the internal blade-operating mechanism. This oil has a viscosity of approximately 1700 S.S.U. at 100 F. Whenever the runner is dismantled for inspection or repair, it is necessary to remove this oil, and since there are approximately 1500 gal of oil in each hub, the Authority salvages it for re-use.

A black steel pipe header is installed in the access gallery located below the units in each plant. Branch headers lead from this line to the draft-tube access doors of each unit, and connection to the hub is made with a flexible hose. An 8-gpm motor-driven screw-type portable pump and two portable storage tanks are provided for transporting and storing the oil during the dismantling of the unit. Because of the infrequency of this operation, the storage tanks and the pump were made portable so that they may be transferred from plant to plant as required. Two storage tanks were supplied to reduce the volume of each tank to facilitate handling.

Raw Water. Raw water is used in the Authority's plants for cooling water for the main generators, for the air compressors, and for the air-conditioning equipment, and in some plants for fire protection, for lubricating the turbine guide bearing, and for supplying make-up for the treated-water system.

In the low-head plants water is taken from the scroll case of each unit and pumped through a multiple basket strainer having $^3/_{16}$-in. openings to a header leading to the station system. One pump is located at each unit to insure a positive cooling-water supply, and a stand-by pump is installed in the service bay of each plant. This latter pump is connected to the forebay by a separate intake and can supply any unit with cooling water in an emergency. All the pumps are connected into a header running the length of the powerhouse so that the chances of any one unit being without cooling water are remote.

The pumps are horizontally split-case, double-suction, single-stage, volute-type centrifugal units. Specifications include enclosed bronze impeller with wearing rings, bronze shaft sleeves through the stuffing box, water-seal piping, and deep stuffing boxes. Experience has proved that this type of pump will give years of service with little maintenance except occasional repacking or lubrication of the bearings. A booster pump is installed in each plant service system using raw water where the forebay pressure is insufficient for a gravity supply. Sometimes the operating requirements of two or more of these systems make it possible to supply them with water from one pump. Quantities involved are usually low, and single-stage single-suction pumps are used. The Authority has found the close-coupled type of pump very satisfactory for this service.

In the high-head plants a separate intake from each unit pen-

stock is connected to a central manifold from which the individual systems are supplied, with pressure-reducing valves installed as required. An air-cushion chamber is installed on the manifold to absorb the water hammer caused by the operation of the system. When the raw-water system supplies the make-up for the treated-water system, intakes at different levels are provided in the dam to enable the operator to take advantage of the varying water temperatures, turbidities, and chemical contents of the lake water at different levels.

The Authority uses black steel pipe for exposed raw-water piping, except that galvanized steel is sometimes used in the smaller sizes. Welded joints are used, except that flanged joints are used around equipment and valves. Gaskets are $^1/_{16}$-in. red rubber. Raw-water lines buried in the ground are cast iron, bell and spigot, in accordance with standard waterworks practice. Black wrought-iron pipe is used for buried lines in sizes $1^1/_2$ in. and smaller, for sprinkler and general yard service.

Lines are insulated in locations where sweating of the cold pipe would prove objectionable. Standard commercial insulating felt molded in 3-ft lengths and covered with 8-oz canvas jacket is used for straight runs of pipe. Fittings and irregular surfaces are covered with a layer of hair felt sealed with a waterproof-tape wrapping and a coating of asphaltic sealing compound. Insulation of 1 in. thickness has been found sufficient to prevent sweating for the water temperatures and air humidities encountered in the low-head hydro plants, but $1^1/_2$ in. of insulation is necessary in the high-head plants because of the colder water. Regranulated cork has been used in some instances to prevent sweating, but unless it is applied very carefully and built up to a thickness of $^1/_4$ in. or more, it is not as satisfactory as hair felt. This is especially true in the high-head plants where water temperatures sometimes go as low as 36 F. Raw-water lines subject to freezing temperatures are insulated with built-up hair felt. The required thickness is a function of the temperatures encountered and the amount of water passing through the line and is investigated for each condition.

Treated Water. Treated water is used in the various hydro plants for all sanitary services, and in some plants for fire protection. Whenever possible the Authority obtains its treated water from a near-by community, even if this involves laying a mile or two of transmission main. We have found it to be more economical to purchase water in this manner than to install a treating system in the plant, requiring the services of an operator. However, it has been necessary to install water-treating systems in most of the projects because of their isolated locations.

At some projects the plant operators live close at hand and use water from the system. This increases the required capacity to the point where a conventional rapid sand gravity filter plant, with mixing chamber, coagulation basin, dry-chemical feeders, and chlorinator is justified. The water treated in this area is such that alum and soda ash or lime are the reagents used. At some of the projects the demand is 10 gpm or less, and pressure filter plants are installed. Originally, pot feeders actuated by differential flow across the orifices were installed for chemical feeding in the pressure filter plants, but our experience with them has not been satisfactory, and they have been replaced with solution-feeder pumps. Pot feeders are difficult to keep regulated, especially when the temperature of the water supply varies considerably as it does with intermittent use.

System pressure is obtained by using elevated storage tanks which usually are transferred from the construction activities at the project. At some of the high-head plants, where such a tank was not available and where raw water for fire protection could be obtained from pond storage, a pneumatic tank was installed for the treated-water system pressure. However, the controls for these tanks require a great deal of attention to keep them in proper working order, and an elevated storage tank is much preferred for this service.

The foregoing comments for pumps, piping, and insulation of the raw-water system apply to the treated-water system also except that in the latter case more galvanized-steel pipe is used.

Fire Protection. Raw water is used for fire protection in all plants where the minimum lake level provides sufficient pressure. The Authority has adopted 40 psi at the hose nozzle as the minimum pressure for this service, but a pressure of 60 to 70 psi is preferred and is used when obtainable. In plants where this pressure is not obtained, fire protection is obtained from the treated-water system or by means of a booster pump.

Fire-hose racks containing 50 ft of $1^1/_2$-in. unlined linen hose with cast-brass nozzles are located throughout each powerhouse at strategic points for inside fire protection. Standard 4-in. A.W.W.A. fire hydrants, fitted with two $2^1/_2$-in. nozzles, are located throughout the plant area and switchyard. A fire-hose cart equipped with a reel and three 50-ft lengths of $2^1/_2$-in. double-jacketed, flat-cured, cotton, rubber-lined hose with rocker-lug couplings is provided for switchyard fire protection. This is supplemented by a wheeled cart containing two 100-lb cylinders of CO_2. National standard fire-hose threads are used for the $2^1/_2$-in. hose and standard-iron-pipe threads for the $1^1/_2$-in. hose. Standard underwriters' play pipes are provided for outdoor fires, except that for electrical fires a nozzle is used which atomizes the water spray to the point where it will not conduct electricity.

Considerations were given to installing built-in fire-protection systems, using either water or CO_2, in the switchyards. These were ruled out because the remote possibility of these fires would not justify the cost of the installation. Sometimes transformers are installed very close to the powerhouse, as on the draft-tube deck. In such cases a fire might cause considerable damage, and built-in water systems, using fog nozzles, are installed. These systems are set off either manually by remote control, automatically by thermostats, or by the tripping of the transformer differential relay which is actuated by a short circuit in the transformer.

Carbon Dioxide. In addition to water fire protection, a complete CO_2 system is provided for each plant. This system protects the main generators, the oil-purification room, and the oil-storage rooms. The CO_2 system is designed in accordance with the standards of the National Board of Fire Underwriters for class A systems, which calls for total flooding of enclosed spaces.

A central supply of 50-lb storage cylinders sufficient to provide the gas concentration for one generator called for by the standards mentioned, is connected to all the generators by a complete piping system. This system is energized either manually by remote control or automatically by thermostats located in each generator. A separate system of cylinders and piping is provided for the oil-purification and storage rooms. It is controlled either manually or by thermostats in the room being protected. When this system trips off, all doors and openings automatically close to confine the gas, and pumps, ventilating fans, and other moving equipment shut down. The gas-discharge nozzles in an oil-purification room for one plant may be seen in Fig. 6. Portable containers of carbon dioxide in the 4- and 15-lb sizes are located at various points throughout the powerhouse to supplement the built-in systems.

Drainage and Unwatering. Roof, deck, and floor drainage in each plant is discharged either to the forebay or the tailrace whenever possible; however, it is necessary to carry some of the drainage to the station sump during periods of high tail-water levels. Galvanized steel pipe usually is used for roof drains, and black steel pipe for deck and floor drains. Screwed cast-iron drainage fittings which have recessed shoulders are used for all

systems. Expansion of roof-drain riser pipes is taken care of just under the roof either by fitting offsets in the pipes or by patented slip joints made for that purpose. Lines are uninsulated, except that deck drains are insulated against sweating when they run above false ceilings in the office areas.

Lead and special-alloy cast-iron lines were originally installed for battery-room drains as a protection against acid. This has been changed to standard steel pipe because the weak concentration of the acid solution does not justify the extra cost of special pipe.

The station sump in each plant is unwatered by two 300-gpm, float-controlled, deep-well-type, vertical-shaft turbine pumps operating in echelon. This type of pump keeps the motor above the wet conditions of an open sump. Very little sand or abrasive matter is present in the water, so enclosed or semienclosed impellers are specified. The pumps are bronze-mounted and oil-lubricated automatically by a solenoid valve energized with the motor circuit.

At times it is necessary to unwater the draft tube of a unit for inspection. Each unit draft tube is connected to the station sump with a large-size cast-iron line containing a sectionalizing valve. The first project of the Authority had the outlet in the bottom of the draft tube, but this soon filled up with sediment and later projects have this outlet about 15 in. from the bottom of the draft-tube floor. Most plants have two deep-well-type vertical unwatering pumps which range in capacity from 2500 to 5000 gpm, according to the volume of the draft tube. They are manually operated and can augment the station sump pumps in an emergency. In those plants where sufficient head is available, unwatering is done by eductors. Since this pressure water comes from the unit penstocks and since it is possible for the penstocks to be empty, the station drainage eductor is supplemented by one motor-driven sump pump. No supplementary pump is installed for draft-tube unwatering as unwatering operations may be scheduled for the times when a penstock is full of water.

Piezometers. The Authority installs piezometers in the various water passages at each plant to check the hydraulic performance of the units, penstocks, and spillways and to operate flowmeters. These lines are $^3/_4$-in. type K, extra-heavy, hard-copper tubing with solder-joint streamline fittings. Lines are installed carefully to avoid pockets and have a minimum pitch of 1 in. in 10 ft from the connection at the water passage to the terminal board.

Plumbing. In general, the design of the plumbing systems in the hydro plants of the Authority follows the "Recommended Minimum Requirements for Plumbing" established by the Subcommittee on Plumbing of the U. S. Department of Commerce.

Water closets and urinals are provided with flush valves, with those on the urinals being foot-operated. All lavatories are equipped with mixing faucets. Hot water is supplied by thermostatic-controlled tanks with immersion-type elements. These tanks vary in size from 10 to 120 gal. Where the hot-water lines are of considerable length, a small circulating pump is installed; however, in some instances it has been found more economical to purchase more than one heater, thus eliminating long runs of piping. A mixing valve is used in the showers to prevent the possibility of scalding. Drinking water is furnished by self-contained electric coolers located throughout each plant. Wall fountains supplied with chilled water from the remote connections on the water coolers are also used. Acid-resisting, enameled, cast-iron sinks have replaced stoneware sinks which were used in the battery rooms of some of the earlier hydro plants.

Type K, extra-heavy, hard-copper tubing with solder-joint fittings is used for all sanitary-water service because its small additional cost is justified by its longer life and its ease of installation. Air chambers 18 in. long are installed as close to the fixtures as possible to absorb the surges caused by quick-closing faucets or valves. Water pressures are maintained at approximately 50 psi, with no pressures exceeding 85 psi at a fixture. Excessive pressure results in leakage, water hammer, and high maintenance costs. Valves are provided at each fixture to permit repairs without shutting off a whole group of fixtures. Vacuum breakers are installed on all fixtures that are directly connected to the water supply to prevent polluted water from being siphoned into the water lines. Although ordinarily the pressure in the water lines prevents the entrance of polluted water, sometimes a partial vacuum occurs which causes siphoning unless vacuum breakers are installed. Floor drains in the toilet rooms have been eliminated in the later plants because they are so infrequently used that water evaporates in the traps and sewer gas enters the room.

All exposed soil and waste lines are standard-weight, galvanized, wrought-iron pipe with black, screwed, cast-iron drainage fittings. Extra-heavy cast-iron soil pipe and fittings are used for embedded lines. Galvanized wrought-iron pipe with black malleable-iron fittings is used for vent lines; where possible, the vents are all connected to the main vent stack to reduce the number of pipes projecting above the roof. A septic tank is installed in each plant with effluent discharged to tail water.

Hot-water piping is insulated with standard molded 3-ft sections of 6-ply preshrunk corrugated asbestos paper, 1 in. thick, and covered with 8-oz canvas pasted on. Fittings in hot-water lines are covered with insulating cement.

Heating, Ventilating, and Air Conditioning. Since the powerhouses are relatively large, with limited occupancy, and the materials of construction are such as to absorb large quantities of heat, the power requirements for general heating to comfort conditions are greater than can be justified. Consequently, only those areas where attendance is required are heated to 72 F, while the rest of the spaces are heated only as required for the relief of dampness or excessive chill.

All heating is by electric-resistance heaters. Except for the air-conditioned areas, heaters, in general, are thermostat-controlled, fan-type, 440-volt, three-phase units, with auxiliary on-off-auto manual switches. In some of the smaller areas 220-volt, single-phase, thermostat-controlled heaters are used. They are either gravity convection heaters recessed in the walls or suspended fan units as space or architectural considerations may require. In addition to these permanent heaters, outlets are provided throughout each powerhouse to which portable electric heaters may be connected as desired. In some of the powerhouses air used for ventilating electrical equipment is recirculated, thus utilizing the heat dissipated. In one plant this reclaimed heat amounted to more than 100 kw.

Ventilation is provided in the several areas of each plant according to the need for human comfort, for the dissipation of heat from electrical equipment and solar radiation on roofs, walls, and decks, and for the relief of dampness. In a number of plants where the arrangement and design of the electrical equipment require, parts of the electrical apparatus, including the main generator leads, are ventilated to prevent damage from overheating. Ventilation is provided in the tunnels and lower galleries for the relief of excessively damp and stagnant conditions.

The scheme of ventilation is a problem which must be solved in each individual plant. The usual practice of the Authority is to introduce air into the generator room and lower parts of the service bay and to exhaust this air through the other spaces to be ventilated by separate fans. In a few plants the fresh air is introduced by gravity, but in most powerhouses a number of supply fans are employed. The arrangement of each powerhouse usually is such that most of the more important spaces adjoin the generator room or are connected to it by open passages. These spaces are grouped together according to location and similarity of ventilating requirements into a number of groups, and each group is

served by a separate exhaust system. In the semienclosed type of hydro plant, where the intake deck is just above the generators, the excess heat from the generators and from solar radiation on the deck above escapes through louvers in the generator hatch covers over the machines. These louvers may be closed in winter, if desired, to conserve heat.

For convenience of maintenance and for economy of space, all the fans in the powerhouse are grouped usually into two separate fan stations. Fig. 7 shows an exhaust-fan station for one plant. It may be seen from this view that both direct-connected and

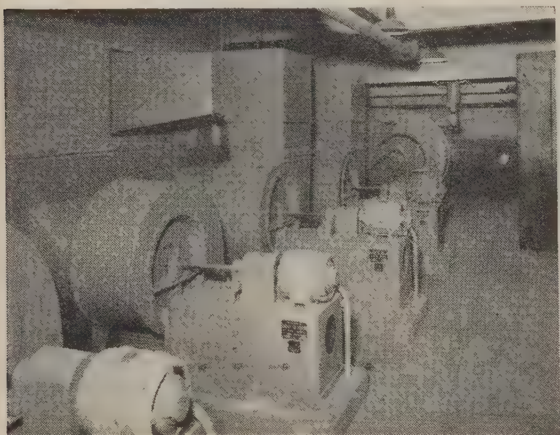

Fig. 7 Exhaust-Fan Room

belt-driven fans are used. When the discharge pressure is fairly constant, fans with forward-curved blades at low rotative speeds are sometimes used. However, most of the fans used by the Authority have backward-curved blades because of their high efficiencies over a wide range of performance and because of the nonoverloading characteristic of that type of blade. It is also better suited to high speeds and hence more adaptable to direct connection. Inlet dampers are used where close control of the discharge pressure or of the delivery of a fan is desired. These dampers are operated by either a pneumatic or an electric motor actuated by the discharge pressure. Resilient bases, usually rubber-mounted, are used under fans when it is necessary to eliminate vibration or reduce noise.

Air conditioning is provided in certain spaces of each powerhouse for the protection of delicate electrical equipment and for human comfort. Because of variations in the heating and cooling requirements of the different parts of the powerhouse, the air-conditioning spaces usually are divided into three systems. One system serves the control room and its related spaces, another system serves the office areas, while the third system serves the public spaces, including the lobby and entrance vestibules. Other spaces, such as the telephone-equipment room, the laboratory, the assembly room, and the first-aid station, are served by one or more of the three systems. The control-room-system areas are grouped together because with their limited outside exposures and heavy heat losses from electrical equipment, they may require cooling at times when the other spaces require heating. The office system areas are served together because of similarity of exposure and thermal load, and the spaces served by the public spaces system are grouped together because of their proximity.

The individual air-conditioning systems may be used for ventilating, heating, and humidifying, or cooling and dehumidifying as required. Electric blast heaters are used for heating, and their operation is thermostatically regulated with auxiliary manual control. Humidification is provided by discharge of live steam generated by an electric immersion heater in an open pan in the plenum of each system. Cooling is by finned-type surface coolers, using chilled water in the coils. In the high-head plants where storage water is available at 55 F or less, lake water is used; in the other plants water is chilled by mechanical refrigeration.

Each of the air-conditioning systems can be placed on the heating, cooling, or ventilating cycles as desired and the control and operation of each is independent, that is, one system may be operating on the heating cycle while the other systems are on the cooling or ventilating cycles. Each system is complete with fan, electric blast heaters, humidifier, cooling coils, and filters, together with the manual, thermostatic, and other automatic control and safety devices necessary for its operation. Fans for air conditioning have two-speed motors or adjustable variable-speed motors, with the low speed used for the heating cycle and the high speed used for the cooling cycle.

The air filters are of the dry-filter type with filtering medium of paper, felted cotton, or felted glass fiber. Cell-type construction is used, and spare cells and filter media are provided at each plant.

In those plants having mechanical refrigeration, one water-chilling system serves all air-conditioning systems. The water-cooling equipment consists of one or more single-acting, multicylinder refrigerant compressors, a shell-and-tube-type water cooler, and a shell-and-tube-type condenser, all piped together and assembled as a unit. Welded joints are preferred for the steel refrigerant piping to minimize leakage, but tongue-and-groove-type flanged joints are used for connections to the compressor and refrigerant specialties. Piping smaller than 1 in. is usually extra-heavy copper tubing with sweated joints. The refrigerant is freon-12 which is nontoxic, noninflammable, and nonexplosive. Lake water, usually supplied by gravity, is used for condensing.

The air-conditioning system in each plant is automatic and in order to prevent excessive starting and stopping of the compressor a separate storage tank of chilled water is provided. Water is circulated from this tank by a small pump which responds to demands for cooling water. The chilled-water piping is insulated with cork, glass fiber, or mineral cork, ice-water thickness, and covered with a sealing tape and compound. Supply ducts are insulated with 1-in. boards of the same material and sealed with an airtight coating. Return-air ducts are not insulated. Fans, tanks, and plenums are insulated as required in the same manner as the ducts.

Machine-Shop Equipment. Each plant has a permanent machine shop, usually located just off the erection space on the generator floor. The size of the machine shops and the amount of equipment in them vary in the various plants according to the proximity of outside repair service. However, even in the isolated plants which have the maximum complement of machine tools, it is not intended that they be able to make all major repairs which may be necessary.

Experience has shown that the following list of machine tools is sufficient to take care of all the normal repair work in any plant:

1—8-in. engine lathe
1—9-in. bench lathe
1—24-in. shaper
1—30-in. upright drill
1—10-in. sensitive drill
1—9 × 9-in. power hack saw
1—12-in. grinder
1—portable pipe-threading machine, 1/2 in. to 2 in.
1—tool-post grinder

The larger machine tools are specified for medium-duty general-purpose precision work. In addition to these machines, each

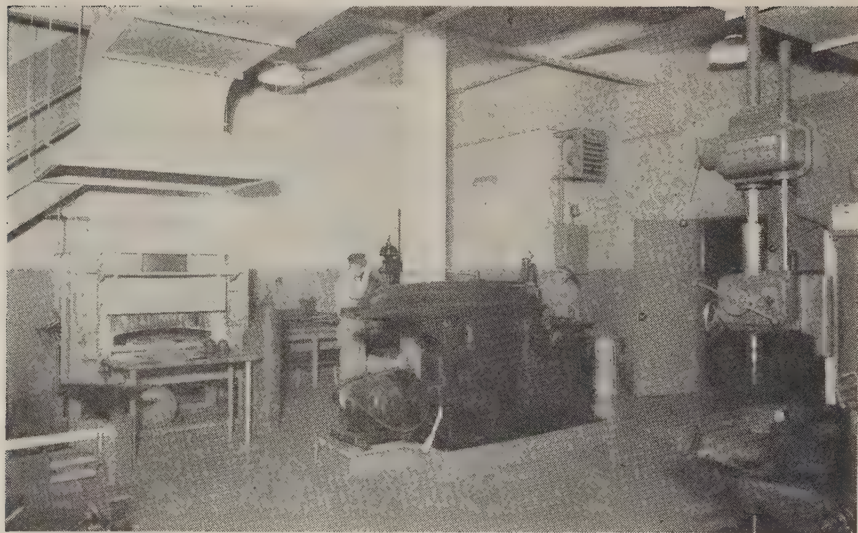

Fig. 8 Typical Machine Shop

plant is provided with a portable forge, blacksmith accessories, and a full complement of small tools. Fig. 8 shows a typical machine shop. The forge in this view has been superseded in later plants by a portable forge.

The author acknowledges valued assistance from members of the mechanical-engineering staff in preparing data for parts of this paper and for constructive criticism of the paper as a whole.

Discussion

Sabin Crocker.[4] The paper is principally devoted to describing the several piping systems required in hydroelectric plants and gives an excellent analysis of the basic considerations for good design of such systems. In general, the writer subscribes to and endorses the author's views on simplicity and neatness of arrangement with a view to improving appearance and at the same time making the purpose of the connections and valving readily apparent. Those interested in furthering a better understanding of the requisites of good design are indebted to the author for having taken the trouble to discuss the fundamental principles of piping layouts in a published paper where the information will be available to young engineers interested in improving their piping technique.

There is only one point noticed by the writer which seems to warrant further explanation. This relates to the following observation:

"In some of the larger-size mains, it has proved advantageous to use spiral-welded pipe. This is especially true in drainage lines embedded in concrete where the cost of steel or cast-iron pipe would not be justified."

The writer would like to inquire whether the foregoing statement should be construed to mean that the author considers it desirable to cast concrete solidly around drain pipes or other pipes conveying fluids. This question is prompted by the fact that cracking or settlement of concrete is apt to fracture any pipe solidly embedded therein, thus permitting the contents to escape or seep away to the general detriment of the piping system and plant. As a protection against trouble of this sort it is usual practice to provide a continuous protecting conduit of larger diameter around a pipe buried in concrete so that the outer conduit can fracture from any moderate settlement without damage to the pipe itself. The writer would like to inquire whether the author recommends dispensing with such outer conduit for drain lines and if so, under what conditions he considers this advisable.

[4] Consulting Engineer, Detroit, Mich. Mem. A.S.M.E.

J. B. Cutler.[5] The author's paper is very interesting and should be of value to hydroelectric-power engineers as it gives a general description of the type and arrangement of mechanical auxiliaries that the TVA engineers consider to be the most satisfactory after many years of operating experience in many plants.

It may be of some interest to mention a few of the mechanical features in our Safe Harbor Hydroelectric Station, which was first placed in operation in 1931, that are different or operate on a somewhat different basis from the TVA equipment referred to in the paper.

Piping and Color Code. The piping systems at Safe Harbor are identified by a color code. The greater portions of these lines, where visible, are painted solidly in the selected code color, and it is our opinion that with this arrangement, quick identification of a service line in an emergency is possible. An exception to this rule is made only for a small portion of some of these lines where, for architectural reasons, another color may be desirable.

All of the valves are identified by tags in a manner similar to that used by TVA, but at Safe Harbor only the valve code number is indicated. The service is readily identified by the solid code color of the pipe line, and the code numbers indicate the main power unit which is served by that line and the position of the valve therein. Odd numbers indicate the supply, and even numbers the return lines. A typical identification number for a valve in the raw-water system, serving power unit No. 3 and being the fifth valve in sequence in the supply line, would be 3-RW-5.

Control Valves. At Safe Harbor, when it is desired to operate a unit as a synchronous condenser, the elevation of water in the draft tube is automatically depressed by the admission of compressed air through the head cover of the turbine. An adjustable

[5] Mechanical Engineer, Pennsylvania Water & Power Company, Baltimore, Md. Mem. A.S.M.E.

type of reducing valve is used to maintain a constant pressure below the head cover, and although it is necessary to reset this valve for changes in the tail-water elevation greater than 8 or 10 ft, such changes are very infrequent. This system has operated satisfactorily since the units were first installed and no trouble has been encountered. Inspections are made, however, every 3 or 4 years, and as the result of some of these inspections it has been found desirable to overhaul the valve mechanisms.

The float-operating systems used by TVA would have the advantage of maintaining a constant level of water in the draft tubes regardless of the variations in tail-water elevations. It would be interesting to learn from the author whether any mechanical difficulties have ever been experienced in the operation of these floats.

Governor and Lubricating Oil. Similar to the arrangement used in the TVA plants, one grade of oil is used at Safe Harbor for both the governor and the unit guide and thrust bearings, and this oil is handled by one pipe, purifying and storage system. This arrangement has proved to be entirely satisfactory and the same quality of oil has been used since the date of initial operation of this plant. The viscosity of the oil at Safe Harbor is approximately 250 SSU at 100 F, which is somewhat lower than the viscosity value of the oil used in the TVA systems. The oil at Safe Harbor is purified about once a year using a centrifugal type of purifying unit for this operation. It would be interesting to learn how frequently it has been found desirable to purify the oil now being used for TVA.

Runner-Hub Oil. The oil used in the runner hubs of the Safe Harbor turbines has a viscosity of approximately 1600 SSU at 100 F. At 40 F the viscosity is very much higher or somewhere around 19,000. This grade of oil has proved to be satisfactory for this service both during the summer and winter seasons.

The author states that the oil used for this same purpose in the TVA stations has a viscosity of only about 1700 at 100 F, which, it will be noted, is a very much thinner grade than the oil selected for Safe Harbor. In view of this very wide difference in viscosity characteristics any further information the author may submit in regard to TVA operating experience with their oil should be interesting.

Author's Closure

Mr. Crocker's comment relative to the embedment of pipe in concrete is pertinent. The proper procedure under such circumstances should be determined by consultation between the piping designer and the concrete designer. The concrete designer has no wish to design a structure which will crack or settle, as the resulting damage to the dam or powerhouse holds as much or more risk as the damage which may be caused by a cracked pipe. The TVA has made every effort to design concrete structures with a minimum of cracking, and actual experience in the embedding of pipe solidly in this concrete has proved completely successful. However, if the concrete designer decides that unusual settlements may be expected, or if he must put in special contraction joints to care for possible cracking, then the piping designer must be aware of these facts in order that he may design his piping with such special protection as is necessary. It should be pointed out that if the embedded pipe has any bends in it, it would be very difficult and expensive to provide a continuous conduit of larger diameter around the pipe as Mr. Crocker suggests.

Mr. Cutler's comments on this paper are very interesting as the writer formerly was associated with him and helped develop some of the features he mentions about the Safe Harbor hydroelectric station.

The author believes the TVA method of painting piping systems is an improvement over the Safe Harbor method. The Authority's system, which paints all the various pipes with one color (aluminum) with identifying colors at fittings and flanges, provides a more pleasing appearance. This is obtained without sacrificing quick identification in case of emergency, because all valves are painted with the identifying color, and it is the valve, not the pipe, which controls an emergency.

Regarding the identifying valve tags, anything which aids the operator in establishing the function of a valve is to be desired. The naming of a system on the tag performs that function and adds very little to the cost of the tag. The Authority uses the same system of numbering valves on supply and drain lines as Safe Harbor.

We have found the float-operated valve very satisfactory for controlling the water level below the runner when it is operating as a synchronous condenser. It is preferred over the pressure-operated control in that it is much more sensitive and does not need to be reset. No operating difficulties have been experienced with the float-operated valve.

Under normal operating conditions the oil in the governor and lubricating-oil systems is purified once a year, at the time of the annual inspection.

The oil used in the rubber hub has a viscosity of 1700 at 100 F. The 40 F figure as given in the preprint was an error which slipped through all the checkings of this article.

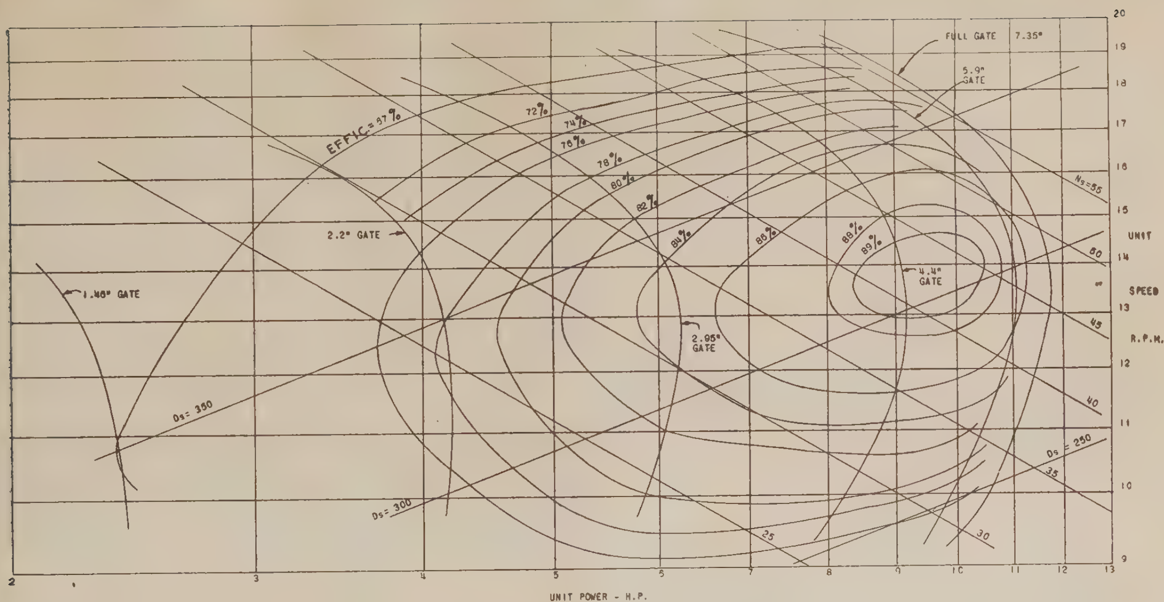

FIG. 1 PERFORMANCE DIAGRAM OF 100-IN-DISCHARGE-DIAM FRANCIS TURBINE
(Efficiencies from model test, not stepped up.)

A Better Method of Representing and Studying Water-Turbine Performance

BY R. A. SUTHERLAND,[1] NEW YORK, N. Y.

The author indicates that the contour form of turbine-efficiency diagram has advantages in giving a clearer picture of performance than the usual efficiency curves. An example illustrates that several different variables can be shown on such diagrams. Formulas are derived for finding the discharge diameters of runners and are illustrated by examples. A simple method of determining the mutual influence of turbine speed and water hammer during transient conditions is illustrated by an example. Finally, the operating stability of a water turbine supplying an independent load is brought forward for discussion.

INTRODUCTION

WATER-turbine performance is usually represented by "performance curves" consisting of a series of power-efficiency curves for different heads; the efficiencies shown may be either "expected" or "guaranteed," and the curves of course apply only to a selected size and speed of runner of a selected type. Such curves are made by "picking off" from test curves which give unit power and efficiency of a given size of runner at various gate openings in terms of "unit speed" or sometimes of "peripheral coefficient." Such curves have been reproduced elsewhere[2] and need not be repeated here.

The performance curves contain the minimum amount of information required by a purchaser and for many purposes are entirely adequate.

Another type of performance curve is in the form of an efficiency contour diagram, examples of which appear in several texts.[3]

The author has found that the contour type of diagram is well adapted for the following purposes:

1 The synthesis of available data on turbine performance.
2 Comparison of different runners.
3 Guide to operation.
4 Study of turbine behavior under transient conditions.

TYPICAL EFFICIENCY DIAGRAM

Fig. 1 represents an efficiency-contour performance diagram for the Norris and Hiwassee turbine model, the data being plotted from the published test diagrams.[2] The size assumed in Fig. 1 is 100 in. discharge diam, to facilitate ready conversion for other sizes. In addition to efficiency, gate openings, and specific speed,

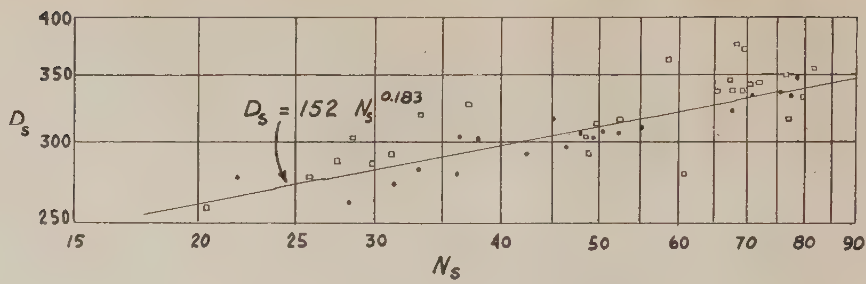

FIG. 2 FRANCIS RUNNERS; DIAMETER NUMBER IN TERMS OF N_s

the diagram also includes some lines representing "diameter number," which is a new concept as far as the author is aware. The expression for D_s is obtained by eliminating head from the basic homologous equations

$$\text{Hp} = A\,D^2 H^{3/2} \quad [1]$$

$$N = B\,\frac{H^{1/2}}{D} \quad [2]$$

where A and B are constants, just as the well-known expression for specific speed is obtained by eliminating D from these equations. By eliminating H from Equations [1] and [2], we obtain

$$D = \left(\frac{B}{A}\right)^{1/5} \frac{\text{Hp}^{1/5}}{N^{3/5}} = D_s\,\frac{\text{Hp}^{1/5}}{N^{3/5}} \quad [3]$$

In the present paper discharge diameters (in inches) are used throughout and values of the diameter number D_s are similarly applicable to discharge diameters (in inches). The symbol D_s has been represented by analogy with the universally used symbol for specific speed, but the author has avoided the use of the word "specific diameter," since D_s is not dimensionally a length, any more than N_s is dimensionally a speed.

The diagram shown in Fig. 1 can readily be converted by the principles of homology to apply to any selected size of runner of the same model type. The values of the efficiency should be stepped up to give an appropriate peak value, as determined by experience or by the use of the Moody formula applied to the original model. The 100-in-discharge-diam runner represented in Fig. 1 would be suitable for use at a normal head of 170 ft, and at a speed of 180 rpm. The unit speed would be 13.8 rpm, and the full-gate unit power at normal head would be 11.8 hp. Allowing a 5 per cent margin in power, the rated horsepower of such a turbine would be 25,000 hp. The D_s value at rated power would be

$$100 \times \frac{180^{3/5}}{25{,}000^{1/5}} = 298$$

SYNTHESIS OF DATA

By tabulating data from a number of turbine tests, expressions can be obtained for various factors in terms of N_s. In the limitations of space only D_s will be considered here. Fig. 2 shows values of D_s for Francis turbines in terms of N_s, each being for rated horsepower, which in the case of models has been assumed 5 per cent less than the full-gate power at rated best speed. The graph can be represented by the equation

$$D_s = 152\,N_s^{0.183} \quad [4]$$

Combining Equations [3] and [4] gives the following expression for discharge diameter

$$D = 152\,N_s^{0.183}\,\frac{\text{Hp}^{1/5}}{N^{3/5}} \quad [5]^4$$

This equation is believed to be more logical as a means of finding the discharge diameter of a Francis runner than others involving head, for the reason that the rated head can always be altered a few feet, while a synchronous speed must be used. The equation can, however, be expressed in these alternative forms

$$D = \frac{152}{N_s^{0.417}} \times \frac{\text{Hp}^{1/2}}{H^{3/4}} \quad [6]$$

$$D = 152\,N_s^{0.583}\,\frac{H^{1/2}}{N} \quad [7]$$

Table 1 shows a comparison of diameters obtained by Equation [5] with actual diameters of a number of turbines, and the results of other methods as noted are given for comparison.

If the specific speed of a Francis turbine be assumed to equal $\frac{632}{H^{1/2}}$, Equation [5] can be simplified (at the cost of some approximation) to the following form

$$D = \frac{1088\ \text{Hp}^{0.139}}{N^{0.722}} \quad [8]$$

Equations [6] and [7] could, of course, be similarly simplified. Equation [8] is represented in Fig. 3.

If a further simplifying assumption is made, namely, that rated load efficiency is 88 per cent, then Equation [8] reduces to the form

$$D = \frac{3.127}{H^{0.0413}}\,Q^{1/2} \quad [9]$$

Values of the coefficient of $Q^{1/2}$ vary only from 2.51 at 600-ft head to 2.81 at 40-ft head, so that Equation [9] leads to a simple "rule of thumb" for finding approximate discharge diameter of a turbine required to use a given amount of water. A simple rule of this type is often useful in preliminary investigation.

For the sake of completeness, equations for the diameters of fixed-blade-propeller and Kaplan runners will be given without description of the supporting data.

For fixed-blade-propeller runners

$$D = 79\,N_s^{0.35}\,\frac{\text{Hp}^{1/5}}{N^{3/5}} \quad [10]$$

For Kaplan runners

$$D = 445\,\frac{\text{Hp}^{1/5}}{N^{3/5}} \quad [11]$$

[4] This equation can be readily solved on a log-log slide rule without resort to tables or charts.

Results obtained by these formulas are given in Tables 2 and 3, respectively, the former of which includes also the results of other methods.

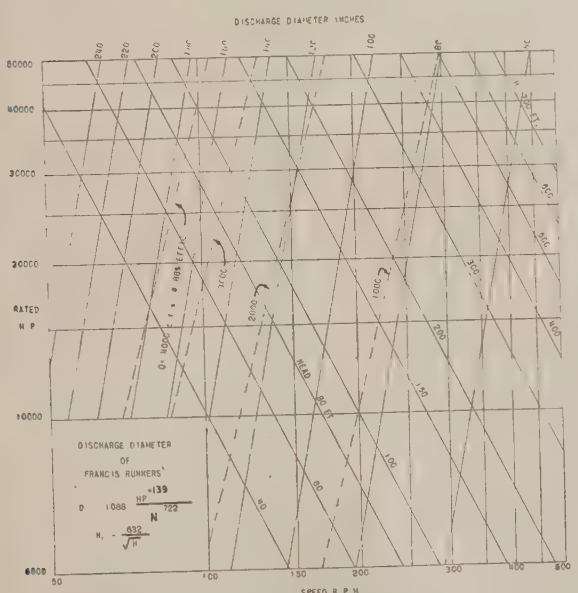

FIG. 3 DISCHARGE DIAMETER OF FRANCIS RUNNERS

The important bearing of sigma value on the best speed of propeller and Kaplan runners militates against obtaining accurate values of diameter for such runners by a formula which does not allow for the effect of the setting.

Equations such as [5], [10], and [11] are useful in the preliminary stages of powerhouse design.

COMPARISON OF DIFFERENT RUNNERS

If diagrams similar to Fig. 1 are available for different runners of approximately the same specific speed, the runners can be compared by superposition of the diagrams. The logarithmic scale enables the "spread" of any efficiency contour (such as 85 per cent or 90 per cent) to be compared as a measure of the percentage of full load over which a given efficiency will be reached or surpassed.

The contour diagram can be used equally as well as the more usual test diagram for "picking off" performance curves of two or more possible runners for given conditions. It can also be used to pick off directly the performance of a turbine at constant output under varying heads, a requirement which may apply to a plant which is used for peaking by being operated a limited number of hours per day at full generator capacity. The last-named pickoff is made by the use of an appropriate D_s line, since these lines represent constant output once the size and speed of the unit have been fixed. It is known that some runners have a better sustained output at low heads than others, and this is at once shown on the contour diagram by the full-gate line continuing to slope upward to the right, instead of bending back to the left. Such a runner might be advantageous in cases of peaking

plants subject to occasional low head, in that a better firm power position could be demonstrated.

In the study of surge-tank stability, the rate of change of efficiency with head (power remaining constant) is one of the factors used.[5] This rate of change may be found directly from the contour curve by use of an appropriate D_s line.

Guide to Operation

Fig. 4 illustrates a typical contour diagram for a Kaplan turbine 132 in. in diam operating at 180 rpm.[6] In addition to efficiency curves, the diagram includes curves for gate opening and blade angle, and the D_s lines have been shown to represent horsepower. It is also readily possible on a large-scale diagram to show discharges and cavitation limits, but they are not included in Fig. 4, to avoid confusion. A diagram of this type is useful as a guide to operating in any desired manner, viz , to obtain highest efficiency, or to maintain a uniform discharge in the river, under varying operating heads.

Study of Turbine Behavior Under Transient Conditions

In so far as the author knows, previous studies of transient conditions in turbines have always been based upon some approximation as regards turbine discharge, and sometimes on a number of approximations. The contour diagram makes it readily possible to study correctly what happens in such cases. To illustrate the procedure, the turbine represented in Fig. 1 is taken.

Steady-load conditions are as follows:

Head, ft	170
Horsepower	25000
Speed, rpm	180
Gate, in.	6.2
Efficiency, per cent	89.3
WR^2, psf	8×10^6

[5] See "Hydraulic Stability," by A. W. F. McQueen, *The Engineering Journal*, vol. 16, 1933, p. 13.

[6] This diagram has actually been falsified from a turbine test and is thus illustrative only.

The effect of gate closure in 4 sec is studied in the following cases:

Case 1. Pressure rise neglected. This case is not attainable in practice, but might simulate conditions if a large surge tank were installed immediately upstream of the turbine.

Case 2. Turbine supplied by a penstock such that the effective characteristics of the water conduit are as follows:

Length, ft	300
Diameter, ft	13
Velocity of propagation, fps	3000

The unit is tripped off the line by relay operation.

Case 3. Similar to Case 2, but the load is reduced by load-limit control, the unit remaining on the line. (It may be noted in passing that according to previous methods the discharge history for this condition would be the same as in Case 2.)

In each case the effect of generator windage has been ignored for the sake of simplicity. It can readily be taken into account by adding another column to Table 4.

Fig. 5 shows the efficiency contours on a network of "unit speed" and "unit power" lines, and the gate lines shown are in accordance with the gate-time curve shown at the left in Fig. 6. The several data given have been selected for simplicity, but illustrate the procedure equally well as though an actual installation were considered. The complexity of the conditions that can be studied are limited only by the patience of the computer.

Pressure changes are determined by the graphical method, which has been described in many published articles.[7] Speed changes are determined by the formula

$$N_2^2 - N_1^2 = \frac{3{,}238{,}000 \times \text{Hp sec during interval}}{WR^2}$$

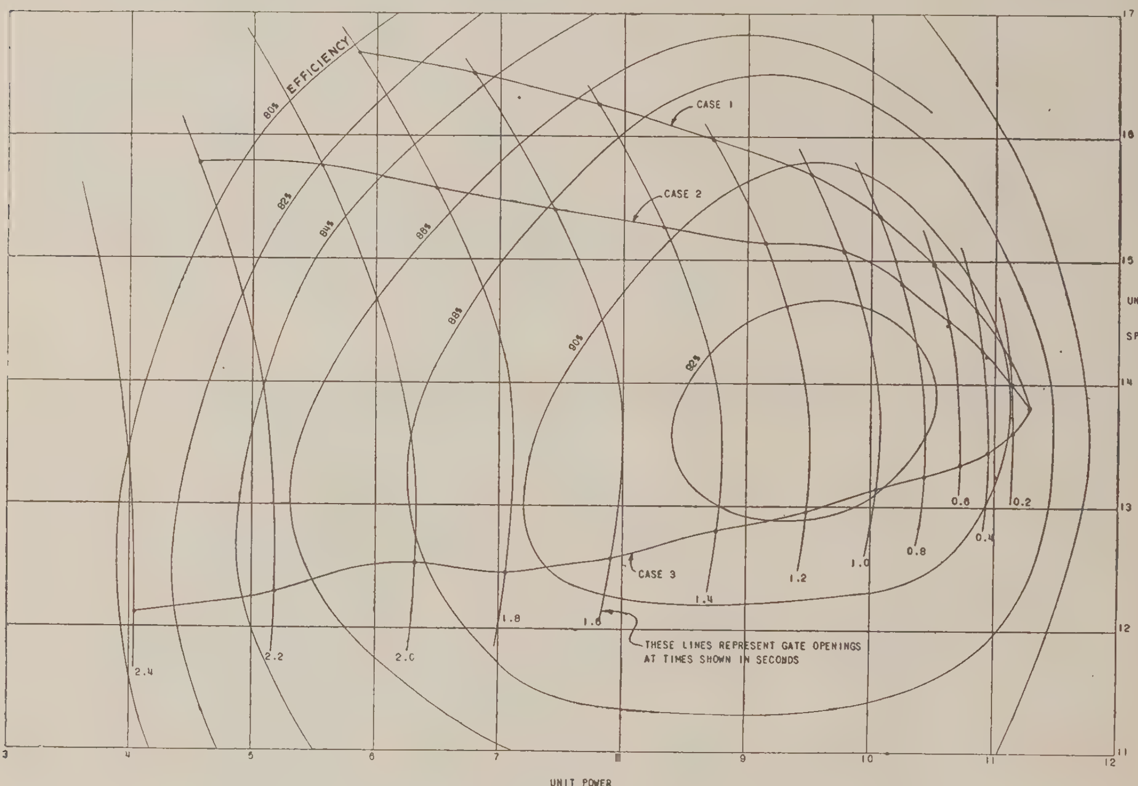

FIG. 5 PERFORMANCE DIAGRAM OF FRANCIS RUNNER FOR TRANSIENT CONDITIONS

Using the interval of 0.2 sec, and inserting the value given for WR^2, this expression reduces to

$$N_2^2 - N_1^2 = \frac{\text{Mean excess hp during interval}}{12.36}$$

The procedure used is a trial-and-error one, illustrated by Table 4, which shows part of the calculations for Case 2.

At each step a head and speed are assumed, and the discharges called for by the turbine diagram and by the pressure diagram are computed. If these discharges are not identical, the head and speed are modified in a direction which will be obvious from the first trial until substantial or exact agreement is obtained.

The results of the three cases cited as examples are shown in Fig. 7. The computation of pressure and discharge has been carried only as far as 1.8, 2.2, and 2.4 sec, respectively, for cases 1, 2, and 3, as indicated in Fig. 5. The remainder of the horsepower curves beyond the computed values can, however, be drawn in (shown broken in Fig. 7) with only slight error and the total speed rise thus determined.

Unfortunately, this method cannot generally be used for Kaplan turbines, because the blade movement does not in general keep time exactly with the gate movement, so that the efficiency-contour diagram (such as Fig. 4) does not hold for transient conditions.

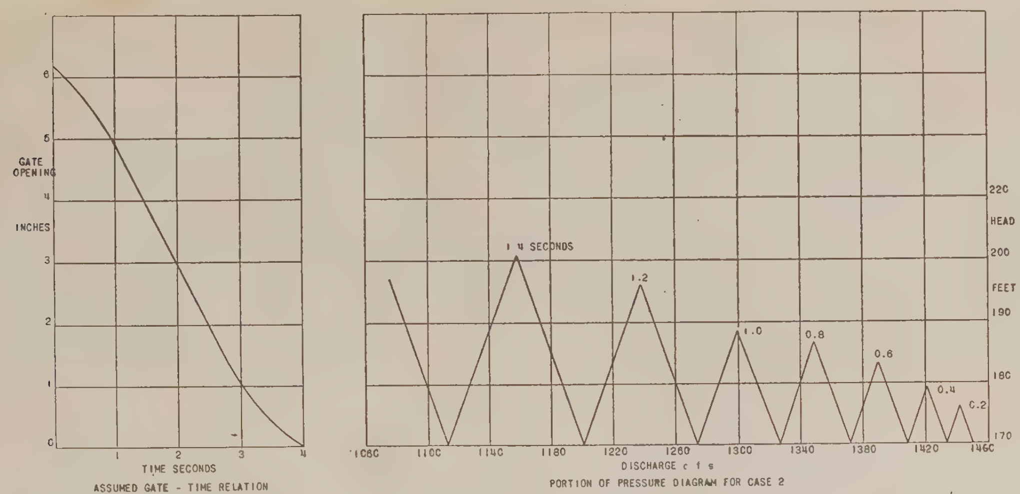

Fig. 6 Gate Relation and Typical Pressure Diagram for Francis Turbine Gate Closure

This method of studying transient conditions is obviously more refined than is generally necessary, but has been of inestimable value in studying one important and unusual installation, in which not only were numerous closure operations studied, but also governing stability of the unit when supplying independent loads. The computed behavior was closely checked by prototype tests.

Governing Stability

Operating stability of a hydroelectric plant generally requires the provision of an amount of WR^2 in the generator considerably in excess of that normally built in by the generator manufacturer. The leading generator makers have tables which show the "normal WR^2" for various sizes and speeds, and Fig. 8 has been prepared by the author to show the resulting regulation constant C. This diagram is useful as a preliminary guide to the amount of excess WR^2 required to give a desired value of C. The regulation of a hydroelectric unit connected to a system has been ably treated by numerous writers. In the exceptional case of a unit supplying an independent load, the stability may require study.

The moving water column contained in the penstock and draft tube represents a considerable amount of kinetic energy, which must be reduced or increased when the turbine gates close or open, respectively, as a result of any governor action, however slight. In the case of gate closure, part of the kinetic energy in the column is in effect transferred to the unit, which is already burdened with the excess energy which gave rise to the speed and gate change.

In the case of the gate-opening movement, the unit needs a quick supply of energy, which the water column is unable to furnish, being burdened with the necessity of increasing its own energy. Thus the water column always acts for an appreciable time in opposition to the governor, and it is easily seen that instability may occur if the water-column kinetic energy becomes too large in proportion to that of the unit.

The author has been able to observe only one case of this kind in practice, in which a unit was supplying a rheostat load and operated stably at small outputs, but became violently unstable as the output was increased. The ratio of the kinetic energy of

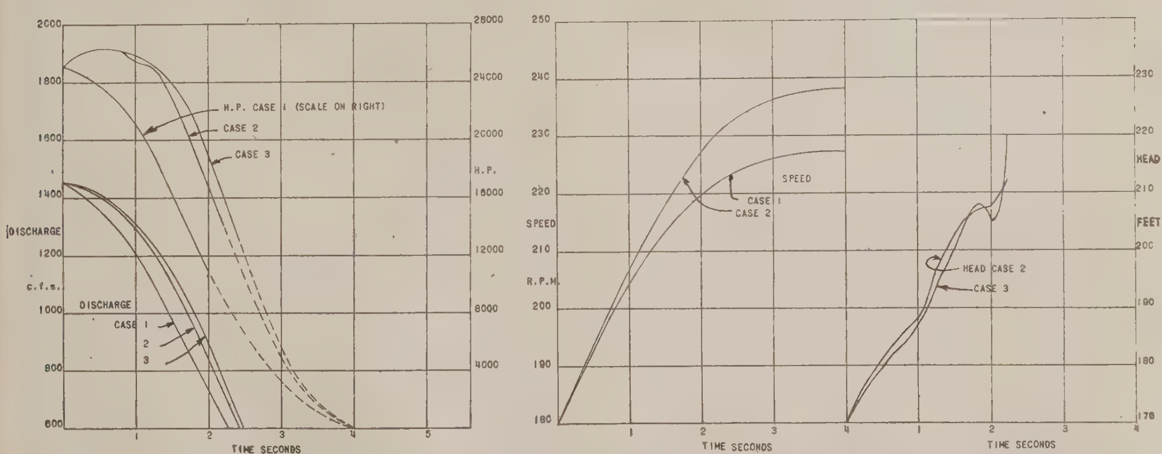

Fig. 7 Discharge, Horsepower, Speed, and Head During Gate Closure Under Different Conditions

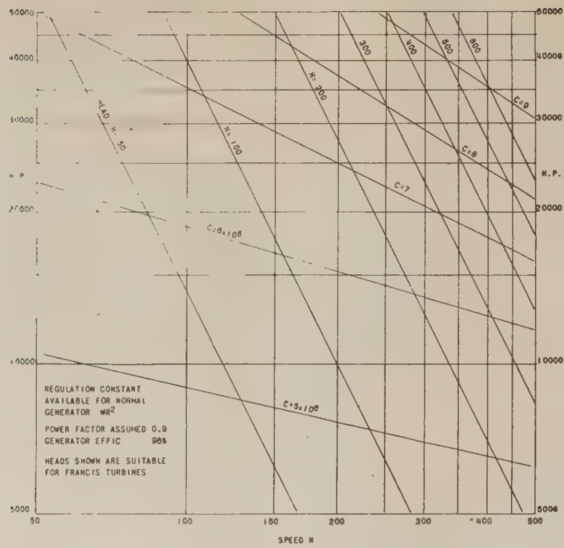

Fig. 8 Regulation Constant Available for Normal WR^2 of Generators

the water column to that of the unit, when instability occurred, was about 0.2. This ratio is obviously not the only factor involved, but is believed to be an important one, and the author suspects, from a study of other plants, that not a few units which now operate very sweetly on the line would be unstable if supplying a rheostat load.

The problem is analogous to but more complicated than the stability of surge tanks; and the author wishes at this time to bring the phenomenon into the open for discussion.

ACKNOWLEDGMENT

The author's thanks are due to Mr. L. F. Harza, who greatly stimulated his interest in turbine performance, and to Mr. George A. Jessop, for suggestions and data.

Discussion

L. F. Harza.[8] The author has urged the use of a valuable form of diagram in which to present hydraulic-turbine test data designed to display the characteristics of the turbine vividly and clearly. This form of turbine characteristic curves was used extensively in the first and subsequent editions of a text by Daniel W. Mead,[9] first published in 1908, on which the writer collaborated, except with a natural instead of logarithmic horizontal scale. The logarithmic scale adds little, if anything, to the diagram except the N_s lines become straight instead of curved.

Many years ago the writer developed standard platting paper for this type of curve with a sufficient range of horizontal and vertical scales so that any turbine then being built could be platted on this paper.[10] The N_s lines were curved because of natural scale. The position of the set of turbine curves on the sheet indicated the type of turbine. Thus a turbine of high unit speed and unit power would be platted, in the author's form of diagram, in the upper right-hand portion of the sheet, and a high head and therefore low-speed turbine in the lower left-hand portion of the sheet.

The author has added one new feature, namely, his D_s curve, whose usefulness the writer is not as yet prepared to evaluate without more experience in using it. The author refers to N_s and D_s characteristics, the former generally known as "specific speed," as not actually dimensional constants. In this the writer differs; N_s is the speed of a 1-hp turbine under 1 ft head, the turbine being of design homologous to the large turbine. Likewise D_s would appear to be the diameter of a homologous turbine which would run at 1 rpm and develop 1 hp. There would appear to be less value, however, in the mental conception of the meaning of this constant as compared with N_s.

The use of the relation curve, Fig. 2 of the paper, between N_s and D_s is not clear except as to the preliminary studies in laying out a hydroelectric station. It cannot be more than a general indication as to the diameter at the outlet of a turbine of an assumed N_s, sufficiently close for a first layout or assumption. It will be noted that the points from which this curve is projected are scattered widely. For example, at N_s = 30 the D_s may vary from about 260 to 300 because of the great difference in dimensions and turbine characteristics of different manufacturers, or the different types of turbines of essentially the same N_s of the same manufacture. For other than the first preliminary studies it is always necessary to use the dimensions of the individual type and size of turbine offered by the manufacturer. The D_s constant might be useful for preliminary studies before this more detailed information is available.

The author offers his Fig. 4 type of diagram as one suitable as a guide for operation, but in the opinion of the writer there is a much better form of diagram available for that purpose.[11] After the turbine is installed and its characteristics known by extrapolation or field test, there is no value in continuing the use of "unit speed" and "unit power" as scales of the operating diagram. The curve mentioned uses the operating head and actual horsepower of the prototype as co-ordinates. Thus at a glance

[11] Ibid., Fig. 5, p. 544.

the operator can pick off the best horsepower at which to run the unit at each head. This should be carried one step further using gross head horizontally and kilowatts vertically, because these are the figures which the operator reads and which he can use without any conversion such as deduction for hydraulic losses to obtain net head, or converting horsepower to kilowatts.

The author presents some applications of his curves to the study of transient phenomena and governing stability which are well worth careful study and application.

Manufacturers generally do not put their test data into the "efficiency-contour" form of curves, or at least if they do, the customer never sees them. The information displayed to the engineer by this form of platting is so far superior to that of the usual form of characteristic curves submitted by a manufacturer, that the extra work of platting is well justified on the part of the purchaser's engineer.

J. D. McLaughlin.[12] The method given for studying the behavior of hydraulic turbine - generator units under transient conditions makes it possible as the author has outlined, to estimate with reasonable accuracy the power, discharge, speed, or head versus time relationships for unusual or unconventional hydroelectric installations.

The behavior under transient conditions of the hydroelectric unit installed at the Fort Peck Project during the war emergency required special analytical consideration in the manner outlined due to the fact that it was installed without the surge tank contemplated in the original design. Prediction of the behavior of the unit under anticipated operating conditions made possible the forecasting of operating regulations and the installation of special accessory features as means of adapting the unit to prevent excessive pressure surges in the penstock. The pressure-surge limitation was met by restricting the wicket-gate closure time to a minimum of approximately 42 sec. Overspeed of the unit, resulting from heavy load rejection at the line circuit breaker, was controlled within reasonable limits by automatic transfer of the generator output to a water rheostat which was preset to dissipate approximately 75 per cent of the load rejected.

The writer, being familiar with the installation, initial tests, and test conditions referred to under "Governing Stability," desires to elaborate upon the causes of instability of the Fort Peck unit when supplying a rheostat load, for the conditions that applied during the tests witnessed by the author. Observations upon which these comments are based were made during the operation of the unit without surge tanks over a period of approximately 3 years, during which time several series of tests were run to obtain specific data for use in designing a continuous-rating water rheostat. Throughout this period the behavior of the unit was one important consideration.

The resistivity of the river water, used in all rheostat tests, is relatively low, being approximately 600 ohms per cu cm. This factor had the effect of making a water rheostat located in the powerhouse tailrace extremely sensitive to fluctuations of the water surface.

The temporary, and what proved upon analysis to be unsatisfactory location of the water rheostat in the powerhouse tailrace during the initial test period undoubtedly intensified and perhaps initiated the instability noted in the operation of the unit supplying an independent load provided by the water rheostat. When operating in this manner, the load on the generator is determined by the depth of the electrode immersion. Surges and surface waves in the tailrace, whether due to the discharge from the adjoining tunnels or from the powerhouse draft tube, changed the depth of electrode immersion, and thus varied the generator load, by changing the water elevation of the tailrace.

An increase in tail-water elevation of 6 in. would produce an increase of approximately 22 per cent in a generator load of 20,000 kw, and would decrease, by the above increment, the head available to the unit. The former would increase the demand for kinetic energy from the water column, while the latter would decrease the energy available in the water column. Conversely, a decrease in tail-water elevation of 6 in. would decrease the load on the generator by approximately 28 per cent and would increase the energy available in the water column. In either case the governor would respond with a gate movement tending to restore the speed to normal, and in both cases would tend to "overadjust" the gate. Since the surging is periodic, it is believed that should the period achieve the proper magnitude with respect to the speed of the governor, serious operating conditions would result from this cause.

C. B. Spellman.[13] This paper arrives at certain new formulas for approximating the discharge diameters of various types of reaction-turbine runners. It appears to the writer that the application of these formulas for diameter is somewhat awkward, because they involve functions other than the basic engineering conditions and on this account the diameter number or the discharge diameter for a given project cannot be determined until one has first determined the specific speed or the speed in rpm. Also, it is suggested that a somewhat more definite idea of the runner size would be obtained if it were expressed as "throat diameter" rather than discharge diameter. The throat diameter seems more definitely fixed by considerations of flow and head, whereas the discharge diameter of a runner having a given throat diameter may vary depending upon the peculiarities of individual runner design. The ratio of discharge diameter to throat diameter might vary from as much as 1.20 down to even less than unity for very low-specific-speed runners.

For purposes of quick approximation of the throat diameter for a given set of basic conditions, the formula

$$\text{Diameter of throat} = \sqrt{\frac{68 \times \text{Horsepower}}{\text{Head}}}$$

has been developed. It will be noted that this formula involves only the two fundamental variables of horsepower and head.

We are indebted to R. B. Willi of the I. P. Morris Department for a very useful formula, involving only these same basic variables, for determining approximately the operating speed of vertical-shaft Francis or Kaplan turbines. This formula is

$$\text{Rpm} = \frac{C \times H^{5/4}}{\sqrt{\text{hp}}}$$

where C is equal to 632 for Francis turbines and 950 for Kaplan turbines.

As a check on the accuracy of these formulas, the writer has tabulated a comparison of the approximate diameter and speed with the actual values, for many of the I. P. Morris installations of both the Francis and Kaplan type (Tables 5 and 6 of this discussion). The tabulation indicates that the error in the formula for throat diameter averages less than 1 per cent and for speed less than 4 per cent. It must be admitted that in some few cases errors of the order of 20 to 25 per cent are encountered, but this occurs only when, for some reason, the specific speed selected for the design was at variance with the permissible value indicated by the "experience curve" of N_s versus head. When more accurate

data are required, manufacturers' recommendations, of course, should be obtained.

The principal application which I. P. Morris has found for the contour type of diagram has been in the Kaplan field, where it greatly facilitates the preparation of expected-performance curves for proposed prototype turbines. Without the contour diagram the preparation of such curves is very laborious, as the basic test data comprise a series of tests for various fixed-blade positions. Thus a performance curve has to be derived for each blade position, and the envelope of these individual performance curves drawn to indicate the performance obtainable with automatic adjustability of the runner blades. The reason for this is that each different blade position, in effect, makes a different runner is so far as performance is concerned. This, of course, does not hold true in the Francis field where the blades are immovable. Hence the Francis performance curve is readily obtainable from a single set of model test readings. For this reason there has not been the same incentive to use contour diagrams for the Francis models as there has been for the Kaplan models.

E. B. Strowger.[14] In discussing turbine behavior under transient conditions, the author makes use of the contour form of turbine-efficiency diagram for showing the performance relations in terms of power, speed, and gate opening. On these diagrams the speed is shown in terms of unit speed and the power in terms of unit power rather than in terms of rpm and power output of the unit under normal head conditions. The writer prefers to show the transient performance in terms of the normal head performance rather than reduce the data to 1 ft head. In this connection he wishes to call attention to the joint paper he wrote with S. L. Kerr in 1926, on this subject,[15] where the step-by-step or arithmetic integration method was first applied to the problem and the solution was first made by a rational method rather than by rough approximation. He also wishes to call attention to a discussion of Arnold Pfau's paper which was published in 1930.[16] The author's method is the same as that shown in these publications except that he has substituted the contour diagram for the runner ϕ curves, and the graphical method of water-hammer determination for the arithmetic-integration method. These substitutions do not change the basic character of the method of computation.

Case 3, cited by the author, assumes that during load rejection the unit remains on the line. Consequently, with the unit connected to a large system, the speed of the unit will remain sensibly constant. However, because the head is increased, due to water hammer, the unit speed decreases as shown by the curve, marked Case 3 in the author's Fig. 5. The author states that according to previous methods the discharge history for this condition would be the same as in Case 2. The writer believes that the method shown in the references cited would give a discharge history which would not be the same as the author's Case No. 2 but would agree with the author's results for Case 3.

It should be pointed out perhaps that the time-horsepower curves for Cases 1 and 2, as shown in the author's Fig. 7, should be modified in the dotted portions to show that the power output becomes negative near the end of the governor stroke due to the overspeed, forcing the governor to close the gates below the speed-no-load point.

Author's Closure

Mr. Harza questions the value of logarithmic plotting of turbine test data. The main advantage, in the author's experience, is the ease of transferring from one size of unit to another. In such case the curves need not be replotted but only the scales need be shifted. Disadvantages are that the portion of the diagram near full gate has the smallest divisions and that the diagram cannot well be extended down to small gate openings. Mr. Harza's definition of "specific speed" is frequently used but nevertheless is believed to be inaccurate, for the insertion of dimensional values will show that it is not a speed. One at least of the makers recognizes this by using the more correct term "characteristic speed number." Similarly the author's term D_s could be called the characteristic diameter number. Its value, as Mr. Harza indicates, lies in giving a first approximation to the size of runner to meet given conditions, just as the N_s parameter is used in finding a suitable speed, and it is believed that the author's Tables 1, 2, and 3 indicate that it serves this purpose. The author's formulas were developed in self-defense against the insistent demand of the structural men for dimensions, in the early planning of hydroelectric projects. One of the engineers of a large public body has devoted a whole book to this and allied questions (Table 1, second footnote). It is true as Mr. Harza points out, that there is quite a spread in the experience values of D_s, but it is believed that this is due largely to the turbine makers' use of developed models for heads or speeds for which they are not ideally suited. It is the author's belief, which unfortunately may never be proved or disproved, that if all turbines were specially designed for optimum operation at their rated head and speed, the spread would be very small.

Mr. McLaughlin's discussion of the Fort Peck installation is of particular interest to the author, who took part in the tests made prior to regular operation. It is hoped that Mr. McLaughlin can be prevailed upon to publish the results of the later tests which he indicates have been made, for this wartime installation was of unusual interest from an hydraulic point of view and reflects considerable initiative and courage on the part of the U. S. Engineer Department. The author is unable to agree with Mr. McLaughlin's suggestion that "the location of the water rheostat in the tailrace perhaps initiated the instability noted." He will, however, agree that it complicated the phenomenon. In a certain report[17] are shown oscillograms obtained during operation both with a tank rheostat (Plate 14, Test D-1) and with the tailrace rheostat (Plate 16, Test H-1) and each shows the same characteristic instability, the period being of the order of 14 seconds. Actually the rate of pressure rise in the case of the tank rheostat appears to be appreciably sharper than in the case of the tailrace rheostat. Instability of this type is comparatively little known in the United States, due to interconnection of plants, but appears to be more familiar to European engineers, and in fact has been ably discussed by Daniel Gaden in a recent text.[18]

Mr. Spellman's contribution is distinctly useful and practical and his formulas have the advantage of being easily remembered. His suggestion that "a more definite idea of the runner size would be obtained if it were expressed as throat diameter rather than as discharge diameter" is no doubt valid, and for a maker's engineer the throat diameter is no doubt the more fundamental dimension. The author's use of his formulas was mainly for the limited purpose of determining in the first place the dimensions of draft tubes, etc., as a means of fixing approximate powerhouse dimensions. This he did by means of various empirical relationships referred to discharge diameter and specific speed. The same purpose could be served if such data were available in terms of throat diameter, which could then be obtained by Mr. Spellman's formulas. The author is interested to note that Mr. Spellman's company values the facility of the contour type of diagram, in the case of Kaplan turbines. It is a fact that the contour diagram is not only capable of containing a surprising amount of information in one diagram without confusion, but is very revealing as to the suitability of a runner for a given head and speed and for this reason has been given the apt name, by Mr. Harza, of the "goldfish bowl" diagram.

Mr. Strowger's eminence in his field makes his contribution especially appreciated by the author, who is glad to state that he regards the first paper cited by Mr. Strowger[15] as the original "gospel" on the subject. Mr. Strowger believes that the methods shown in the references cited by him would give results which would agree with the author's Case 2 and Case 3. Mr. Strowger's Fig. 5 (loc. cit.) gives the gate-time relationship and one turbine efficiency curve, which is presumably taken at the rated head and speed, and therefore at a constant unit speed. It is not apparent to the author that efficiencies taken at a constant unit speed could correctly be applied to the behavior of a turbine whose actual unit speed, on account of the pressure and speed changes, is varying throughout the phenomenon, although no doubt the error involved might be negligible for many purposes. The second reference cited by Mr. Strowger[16] contains a very excellent exposition of his procedure of determining the change in head and speed during the phenomenon of a change in load. It takes into account both the changes in head and speed during the transient as shown by his Tables 2, 3, and 4. Two complete sets of computations are required, the second applying trial and error principles to the first.

The author's procedure seems to be more direct in that each point in the computation is arrived at by trial and error to satisfy simultaneously two sets of conditions, viz., the water-hammer conditions and the turbine characteristics.The accuracy is limited only by the correctness of the physical data and the patience of the computer. The author feels considerable confidence in this method for it was successfully used to predict pressures in the Fort Peck installation under various conditions, and was found to give quite appreciable differences in pressure with the same gate closure, depending on the amount of water rheostat load thrown on the generator during the gate-closing operation. In general, the pressure rise increased as the rheostat load used decreased, although this would not necessarily hold true for other operating heads.

Referring to the author's Fig. 5, if the operating head were different, the starting point of Cases 1, 2, and 3 would likewise be different from that shown, and the lines marked Case 1, Case 2, etc., would cut across the efficiency contours in a different manner and other results than those just mentioned might occur. The Fort Peck tests referred to by Mr. McLaughlin required turbine closures with a water conduit about a mile long and no surge tank, and the element of risk involved warranted the most painstaking investigation prior to embarking on such tests. The author's method also successfully predicted hydraulic instability on rheostat load. This was possible because the slow governor time considered rendered the behavior of the unit amenable to computation by reason of the governor compensation effect being negligible. The author believes that an additional advantage of his procedure lies in its giving a graphical picture at each instant, and this is particularly apparent in studying stability, where what might be called the "history line" (like the lines marked Case 1, etc., on the author's Fig. 5) wanders around the diagram somewhat in the form of a lemniscate.

Mr. Strowger correctly points out that the "tail end" of the author's horsepower curve, Fig. 7, should dip down to a negative value. The excuse for not doing so is that a good runner of the specific speed illustrated would run at speed-no-load with a very small gate (in the case of Fort Peck about 0.04), so that this negative dip would be negligible, and secondly, that makers generally fail to test runners at very small gate openings so that data would ordinarily be unavailable to compute this negative dip, even though it is known to exist. In certain cases, however, it is recognized that this negative power may be of considerable importance, and in any case the existence of the negative portion of the horsepower-time curve would make the speed curve peak earlier, viz., at the instant the horsepower changes from positive to negative.

FIG. 1 GENERAL VIEW OF THE NANTAHALA POWERHOUSE

Nantahala Turbine

BY J. P. GROWDON,[1] R. V. TERRY,[2] AND H. H. GNUSE, JR.[3]

The Nantahala plant of the Nantahala Power and Light Company is located near Franklin, N. C., and was designed by the Aluminum Company of America. The 60,000-hp hydraulic turbine operates under 925 ft rated net head at 450 rpm. The static head on the plant of 1008 ft is the highest for any reaction-type turbine installed in the United States. The design and construction of this turbine and butterfly valve are described, followed by results of the field tests. Operation and maintenance work undertaken since the unit was installed are frankly discussed. The field tests showed an efficiency of 93.7 per cent. Considerable stainless steel was used in the original installation and its use has been greatly extended since the unit was placed in operation.

INTRODUCTION

THE Nantahala hydroelectric development is owned and operated by the Nantahala Power and Light Company, a subsidiary of the Aluminum Company of America. It is situated on the Nantahala River in southwestern North Carolina, where the steep slopes permit a high-head development in a relatively short reach of river. It was completed in July, 1942, and has been in successful operation since that date.

The acquisition and design of this development has been carried on by the owner and its parent company since 1911. In this period of 35 years, many different types of development have been proposed and studied. As finally designed and built, the Nantahala hydroelectric development consists of an earth-faced rock-fill dam, 250 ft high, creating a reservoir with 125,000 acre-ft of usable storage. The water from the reservoir is taken to the powerhouse through an unlined pressure tunnel, approximately 5.3 miles long, and a penstock 1391 ft long. A differential surge tank is located 1991 ft from the turbine. The powerhouse, shown in Fig. 1, contains a single hydroelectric unit, consisting of a 60,000-hp reaction turbine, operating under a maximum static head of 1008 ft, directly connected to a 3-phase 60-cycle generator, with the necessary transformers and auxiliary equipment. The power output is fed into a transmission system so that it is not required to operate the unit when for any reason transmission is interrupted.

A great deal of study was given to the problem of selecting a turbine which would combine the following characteristics: Low cost per horsepower; maximum efficiency; satisfactory and reliable operation.

At this head, either an impulse or reaction turbine appeared feasible. For the total capacity at least two impulse turbines would be required, with an expected efficiency of 88 per cent.

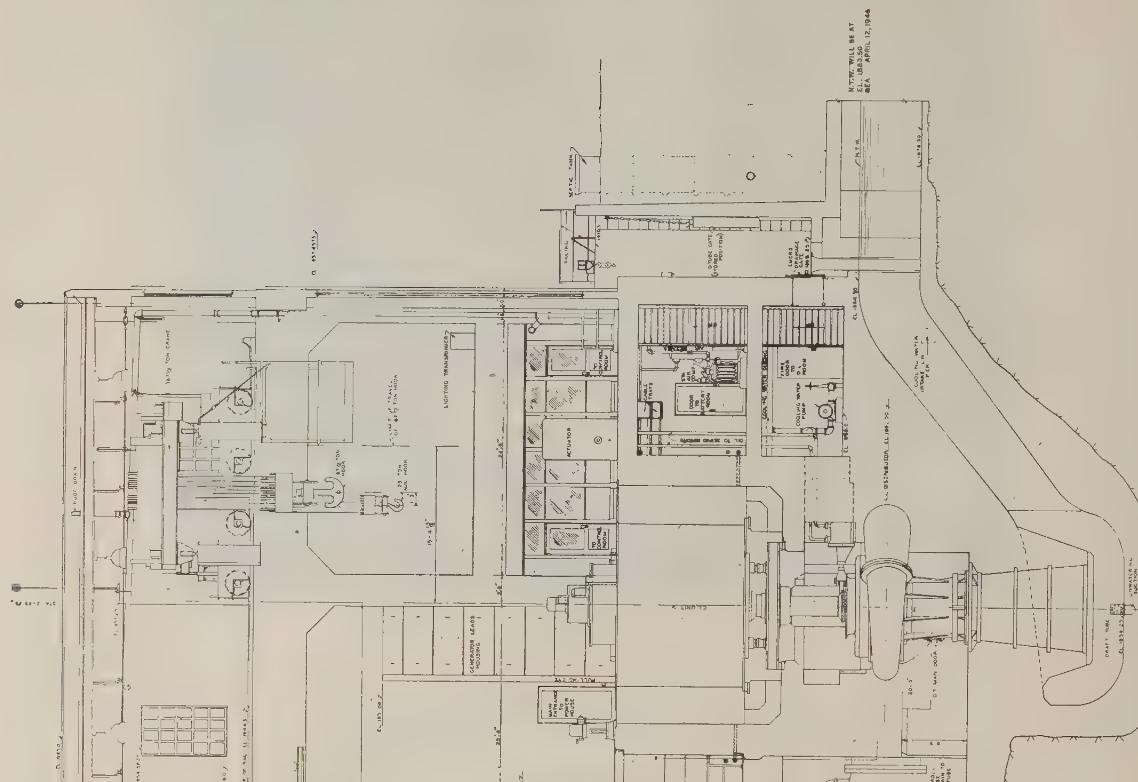

FIG. 2 LONGITUDINAL SECTION THROUGH POWERHOUSE

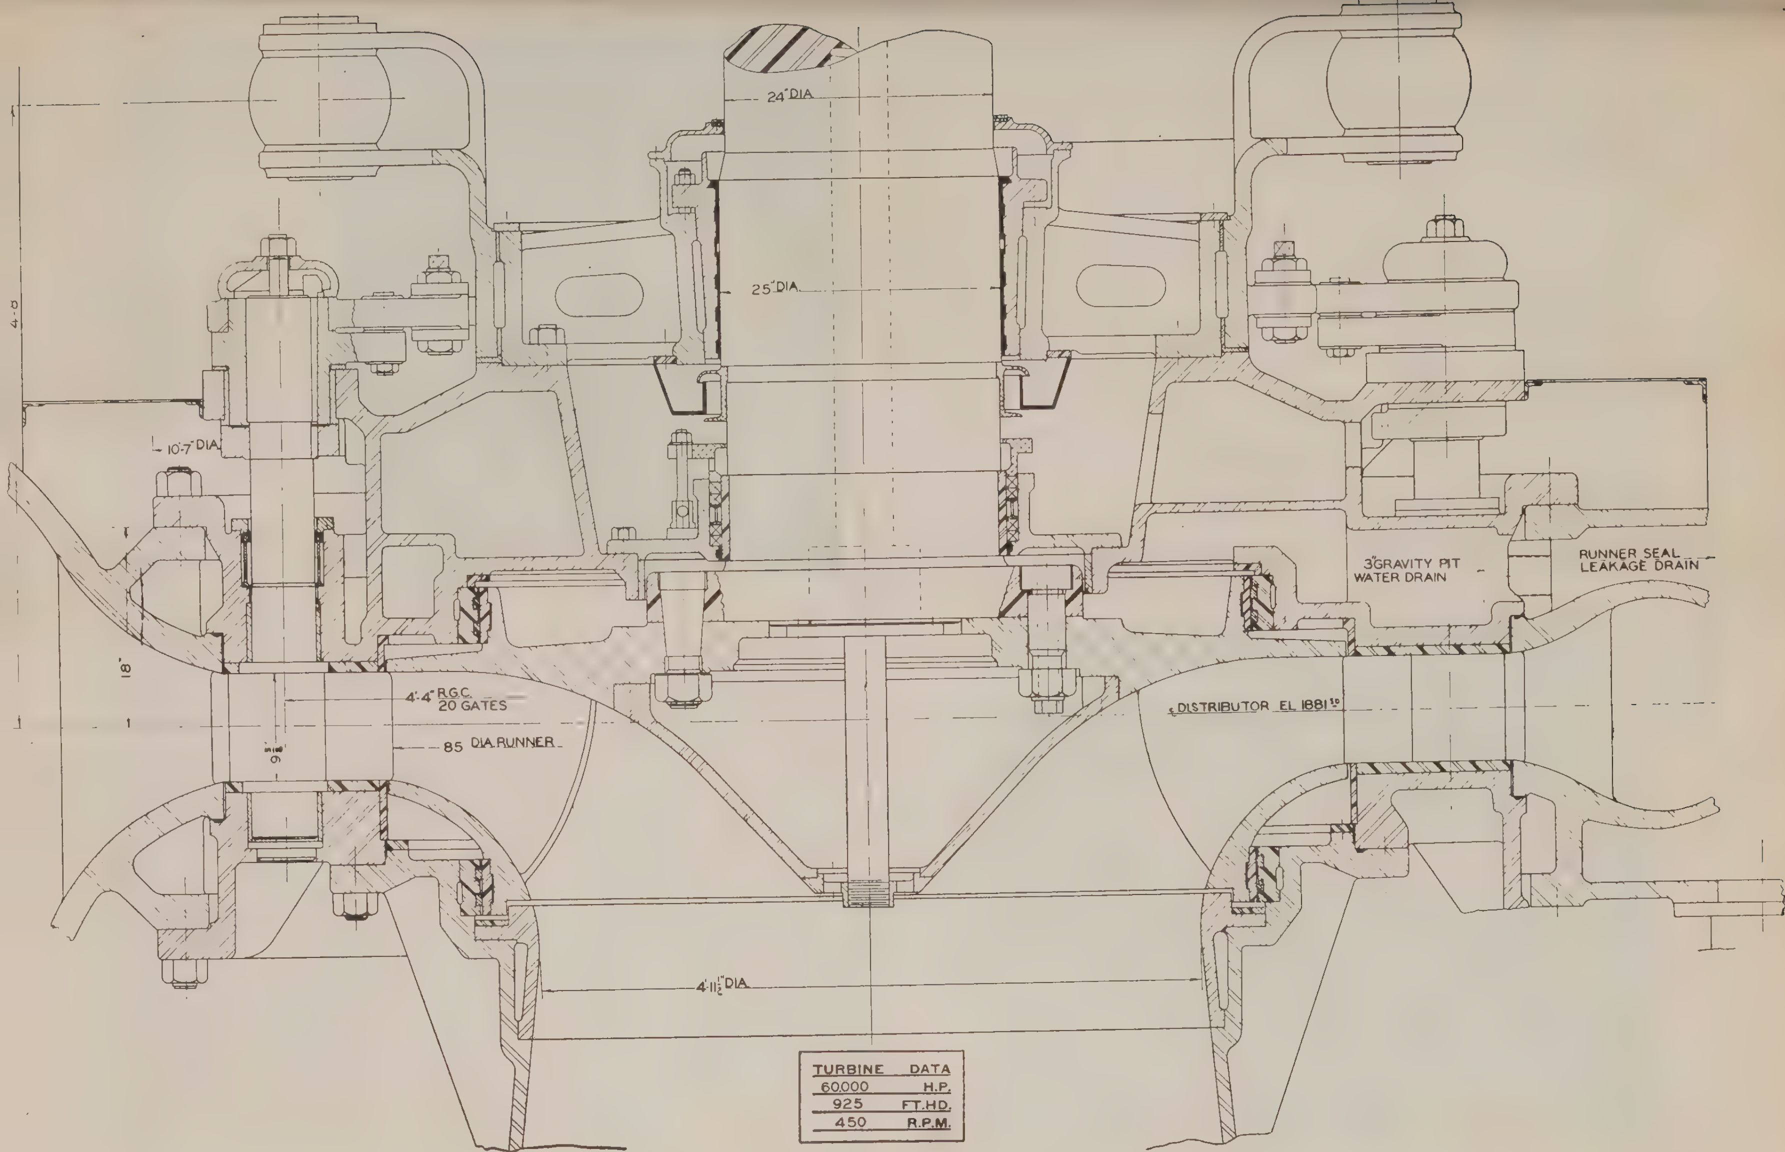

Fig. 3 Sectional View of the Turbine

Since the power requirements did not necessitate operation at low loads, and since the large reservoir provides an opportunity for periodic inspection and repairs, without wasting water, the two units are no more useful than a single unit and would cost considerably more.

A reaction turbine of this capacity, having an efficiency of more than 90 per cent, appeared to be feasible. Due to the permissible lower turbine setting, it would regain a few feet of head which the impulse turbine could not utilize. A single-unit reaction turbine, with its direct-connected generator, would cost considerably less than the two impulse units previously mentioned. It was realized that the head is higher than any other reaction turbine in America, and that reaction turbines under somewhat less head had developed many operating difficulties.

The parent company had had some experience with high-head reaction turbines and believed that as a result of this experience and the increased knowledge of the turbine designers, it would be possible to design and build a reaction turbine which would meet the requirements of the Nantahala hydroelectric development better than any other type and which would be free from serious operating difficulties.

Several turbine manufacturers agreed with this conclusion, and after consideration of all turbine builders' proposals, the contract was awarded to the Newport News Shipbuilding & Dry Dock Company for the design and manufacture of a 60,000-hp (925-ft head), 450-rpm vertical reaction turbine, with all essential auxiliaries, operating under a maximum static head of 1008 ft, and an 8-ft-diam butterfly valve to be located immediately above the scroll case.

Nantahala Turbine

The turbine selected for the Nantahala plant is of the vertical-shaft single-runner Francis type, rated 60,000 hp under a net head of 925 ft, operating at a speed of 450 rpm. This gives a specific speed of 21.6. It is designed for a maximum net head of 1000 ft, the maximum static head on the plant being 1008 ft. This is believed to be the highest-head reaction-type turbine installed in the United States and to be the highest-powered extremely high-head reaction turbine in the world.

The Francis type was selected in preference to an impulse type after giving due consideration to several factors. The efficiency of the reaction-type turbine is several per cent higher (about 4.5 per cent) than that of the impulse type. The speed is considerably higher, resulting in a much smaller and less expensive generator. The unit is sufficiently large so that reasonable clearances could be employed and yet maintain relatively small leakage losses. The disadvantages are that load cannot be changed as rapidly as with an impulse turbine and that there is some element of danger in operating the unit unwatered as a synchronous condenser.

Fig. 2 shows a longitudinal section through the powerhouse. The turbine setting includes a hydraulically operated butterfly valve between the turbine-casing inlet pipe and the penstock, and a cast-steel spiral casing in 3 sections with 20 vanes, one opposite each wicket gate. The vertical part of the draft tube is of the straight conical type, the upper part being of cast steel and the lower part of steel plate. The upper part includes a removable section just below the runner. This permits removing the runner and throat ring from below and gives access for repair or renewal of the seal rings and other work on the turbine without disturbing the crown plate and other parts supported by the crown plate. Downstream of the conical part of the draft tube there is a collecting chamber which discharges diagonally upward and then around a bend to the tailrace. There is one pier in the diagonal portion and bend of the discharge passage. The discharge passage is vented upstream of the bend and near the wall of the powerhouse.

Runner and Seal Rings. Fig. 3 shows a sectional view of the turbine. The runner is of the conventional Francis type of cast steel in one piece, 85 in. nominal diam, with 21 vanes, arranged for a bolted connection to the main shaft. The bolted connection is arranged for easy removal of the runner. There are ten tapered bolts used primarily to take shear and four loose-fitting straight bolts to carry the hydraulic thrust and weight of the runner.

The entrance edges of the vanes are sloped circumferentially and a large radial gap of about 6 in. is left between the runner vanes and wicket gates so as to result in smooth flow from the gates into the runner. This arrangement has proved highly satisfactory and cannot be too greatly emphasized.

The runner carries two straight steel seal rings shrunk on, one on the crown and one on the band. The two rings are of equal diameter to provide good hydraulic balance and at the same time are interchangeable. The rings are placed at as small a diameter as possible so that a small running clearance could be used and the leakage area reduced. A radial clearance of 0.015 in. is employed. The clearances at the periphery of the runner are purposely left large to preserve hydraulic balance. The seal rings are supplied with 80 gpm of clear water through a check valve, piping, and radial holes between the inserts in the stationary seal rings.

Provision is made for checking the seal clearances periodically from above and below the runner, with the turbine shut down. Leakage through the top seal is carried out through the crown plate and a pipe to a point above tail water where the amount of leakage may be observed at any time during operation.

The runner was dynamically balanced and the shaft-connection holes drilled and reamed before shipment to the generator manufacturer. A cast-steel fairwater is bolted to the bottom of the runner. Fig. 4 shows a shop view of the runner and spare runner.

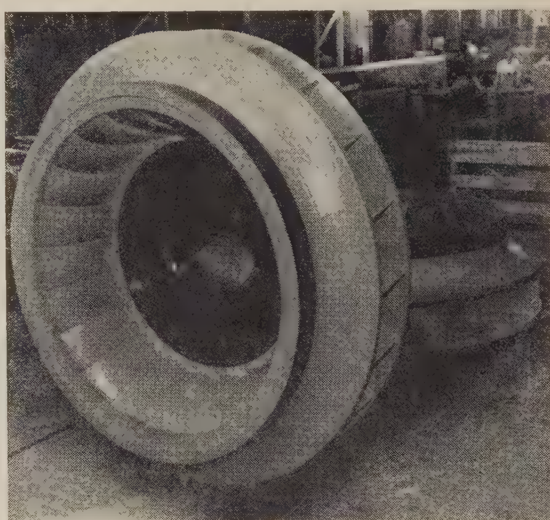

Fig. 4 Shop View of Runner and Spare Runner

Shaft. The usually separate turbine and generator shafts were combined and furnished in one piece by the generator manufacturer. This is practicable since the runner is removed from below. The shaft has a nominal diameter of 24 in. The flange for connection to the runner was drilled and reamed by the generator manufacturer using templates and drilling jigs furnished by the turbine manufacturer who had previously used them in drilling

and reaming the runners. A rather elaborate set of jigs was required owing to the necessity for having the runner, spare runner, and any future replacements interchangeable. The generator builder fitted each runner to the shaft and checked alignments before shipping to the field. The shaft is provided with a stainless-steel sleeve in halves, opposite the turbine stuffing box. A turbine manufacturer's representative supervised the installation of the sleeve and witnessed the shaft and runner alignment.

As usual on large forgings of this kind, a hole was provided in the shaft. This hole was used for certain generator leads and to admit a small amount of venting air to the draft tube through a pipe in the runner cone or fairwater. The hole was also used at first for passing a cable for handling the runner but this was later dispensed with in favor of a jacking arrangement.

Main Bearing and Lubrication. The unit has three bearings, a turbine bearing, a generator-guide bearing below the rotor, and a spherical Kingsbury guide-and-thrust bearing above the rotor. The turbine bearing is of the babbitted oil-lubricated type, 25 in. diam, rather short, being only 16 in. long. The shell is in halves, machine-grooved, tinned, babbitted, bored, and scraped to a clearance of 0.010 in. on diam.

The oil sump is of 74-gal capacity placed in a sector of the crown plate. Oil is supplied to the bearing through a cooler by an a-c motor-driven pump with a d-c motor-driven pump as a stand-by arranged to cut in upon loss of pressure. The pumps, cooler, and gage board are located in an alcove in the turbine pit. The oil supply enters the bearing in an annular groove about one third down from the top, flowing both ways to lubricate the bearing. A reservoir of oil is left at the top of the bearing to act as a supply when changing from a-c to d-c pump or other temporary lack of supply. Excess oil overflows through a pipe to the sump.

Crown and Curb Plates. The crown and curb plates are of cast steel in one piece and of usual construction except that the curb plate is removable from below, after removal of the draft-tube section. This gives access for removal of the wicket gates from below and for maintenance of certain wearing plates and rings under the crown plate.

Wicket Gates and Operating Mechanism. The 20 wicket gates are of forged steel with integral stems. The wearing surfaces at each end of the body of the gates were overlaid by welding with one layer of stainless steel, using a 25 chromium - 20 nickel rod. A total clearance of 0.020 in. was provided.

Each gate has three bearings, one below and two above the body. The lower bearings are greased from below as ample space is available from the passageway around the removable section of the draft tube. Cup leather packing instead of the usual type of square packing is used in the upper gate-stem packing boxes to seal against the high pressures involved. A thrust collar on each gate stem carries the upward thrust against the crown plate.

Each gate lever is made in two sections connected by the usual safety shear pin.

The operating ring and two servomotors, etc., are of usual construction designed for operation with oil at 250 to 300 psi, the displacement of the servomotors being 18.3 gal. In order to suit the design of penstock and surge tank, positive stops were installed on the servomotors to limit the stroke to about 90 per cent, corresponding to a discharge of 635 cfs and about 60,000 hp at 935 ft head.

Governor. The governor is of the Woodward cabinet actuator type with 3-in. pipe connections and rated about 85,000 ft-lb at 250 psi; the governor being designed for a maximum pressure of 300 psi. The minimum time for full gate stroke was specified as 4 sec. However, due to the pipe-line conditions, the closing stroke is limited to 12 sec by $^{17}/_{32}$-in. orifices in the port piping to the servomotors, and the opening stroke to 22 sec by a special small relay valve with limited stroke.

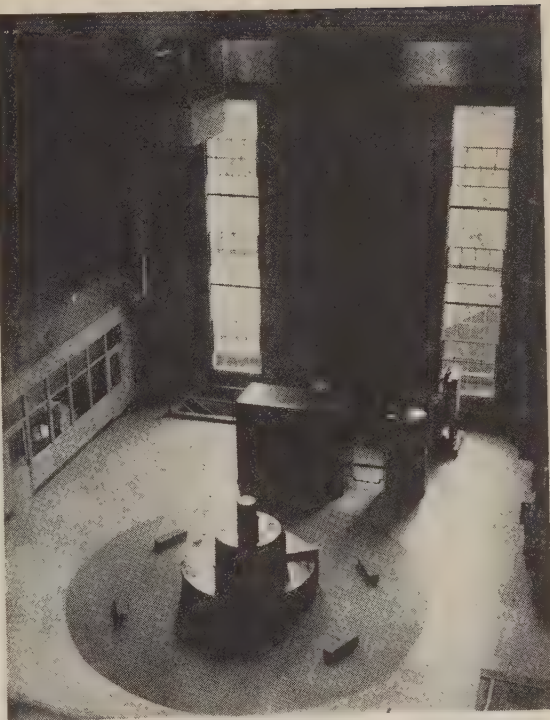

Fig. 5 Interior View of Powerhouse, Including the Governor

The flyballs are driven by a permanent-magnet generator mounted on the generator. Oil pressure is supplied by two 50-gpm motor-driven pumps with echelon control.

The *WR* square of the generator is about 4 000,000 ft^2 lb, giving a regulating constant, WR^2N^2 divided by horsepower, of 13,500,000.

Fig. 5 shows an interior view of the powerhouse, including the governor.

Butterfly Valve. Fig. 6 shows a sectional arrangement of the butterfly valve and operating gear. The valve has a nominal diameter of 8 ft at inlet, reducing to 6 ft 6 in. diam at discharge. Its center line was placed about 20 ft upstream from the center line of the turbine so that there would be no question about the valve disk creating a disturbed flow that would affect the efficiency of the turbine. Body and disk are each in one piece made of cast steel. The shaft is of forged steel keyed to the disk. An 8-in. by-pass is provided for filling the turbine casing before opening the valve, although the valve is designed for opening or closing under full static head of 1008 ft. A 3-in. Crispin air-and-vacuum valve permits the air in the casing to escape and automatically closes when the casing is filled with water. It also admits air when the casing is being drained.

Special care was devoted to the design of the seal rings to reduce the leakage to a minimum and to prevent erosion when the valve was left closed for long periods with the penstock under pressure. Body and disk seal rings are both made of stainless steel of different grades to prevent the possibility of galling. The body seal ring was bored after installation in the body. The disk ring is in halves, secured in its groove, but free to float like a piston ring so that it will adjust itself properly when the valve is closed. This arrangement has proved very satisfactory and there has been little increase in leakage during the 4 years since installation. The choice of stainless steel for the seal rings has proved to be wise.

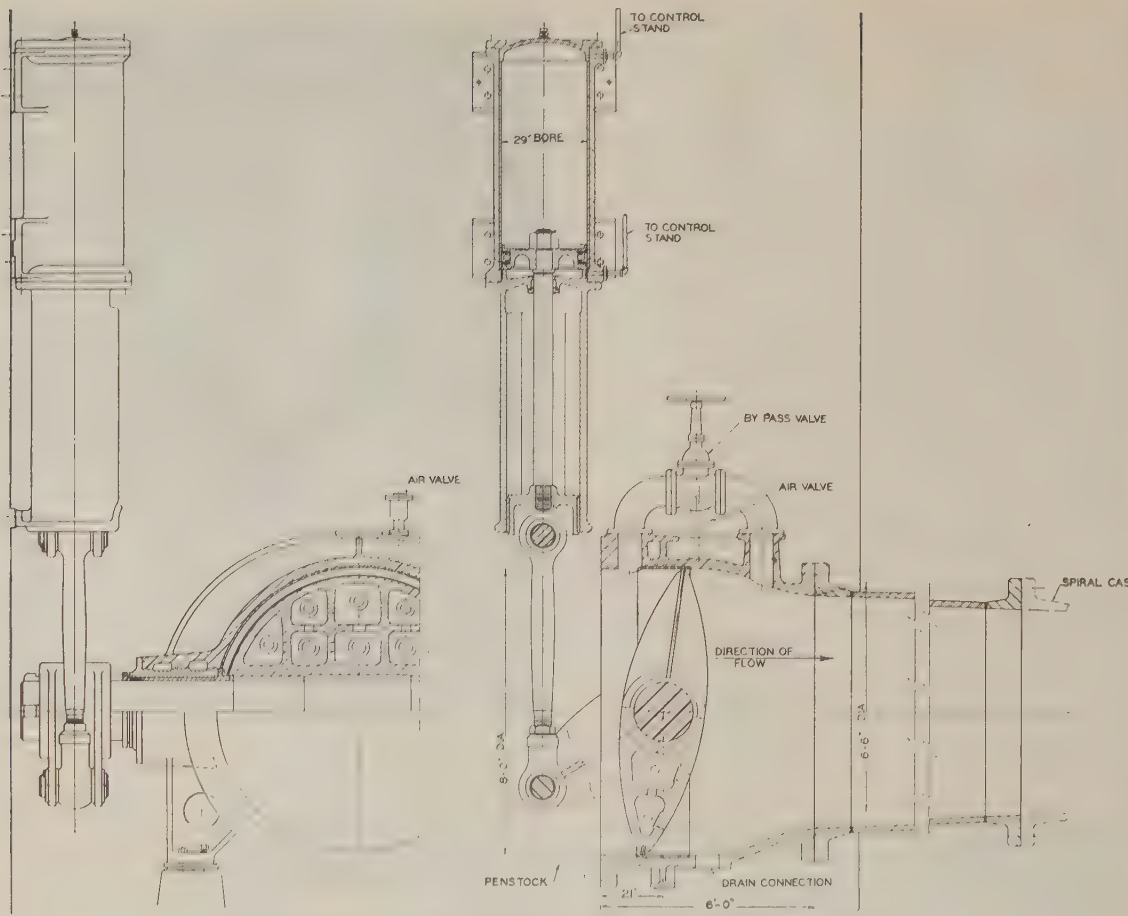

Fig. 6 Sectional Arrangement View of Butterfly Valve and Operating Gear

The valve is arranged to be opened or closed in about 2 min from a control stand on the powerhouse floor, by means of penstock pressure in a bronze-lined cylinder 29 in. diam by about 5-ft stroke. The opening and closing time are limited by the size of the control piping.

Weights. The total weight of the turbine, not including shaft and spares but including governor equipment, was about 300,000 lb. The weight of the complete butterfly valve was about 150,000 lb.

Shop Erection and Tests

The turbine spiral casing, inlet section, and butterfly valve were erected and tested in the shop under a hydrostatic pressure of 700 psi, for 2 hr. Fig. 7 shows these parts assembled with a cast-steel test head bolted to the upstream end of the valve housing. The crown plate and curb plate were in place, and a test ring was fitted between the crown and curb plates opposite where the periphery of the runner would be in the field. The wicket-gate stem holes were temporarily plugged for this test and the butterfly-valve disk was in the open position.

The space between the upstream face of the valve disk and the test head was given a separate test at 700 psi, after closing the disk with a torque of about 80,000 ft-lb. The valve leakage was measured at a pressure of 435 psi, corresponding to full head in the field, and found to be 0.135 cfs. The leakage in the field was much less for then the closing moment was about 10 times as much or 800,000 ft-lb.

A tightness test of 500 psi was placed on the casing and butterfly-valve body in the field before pouring concrete.

Turbine Model and Field Tests

A homologous model was built with a 22-in-diam runner and tested in the manufacturer's hydraulic laboratory before construction of the turbine was started. The homologous parts consisted of all parts which affected the water passages from the inlet to the butterfly valve to the discharge end of the conical draft tube. The model tests were made under a reduced head of about 30 ft. The best efficiency obtained was 89.5 per cent. These tests were made both with and without the butterfly disk in place. No differences in results could be detected.

A complete field test was made in accordance with the A.S.M.E. Test Code for Hydraulic Prime Movers, the water being measured by the Gibson method. Fig. 8 shows the results of the field test, the maximum efficiency being 93.7 per cent.

Sixty-two thousand hp was obtained at 87.5 per cent gate opening which is the maximum gate opening at which the turbine is operated. Above 85.5 per cent gate opening or 60,000 hp, a cavitation noise starts in the draft tube.

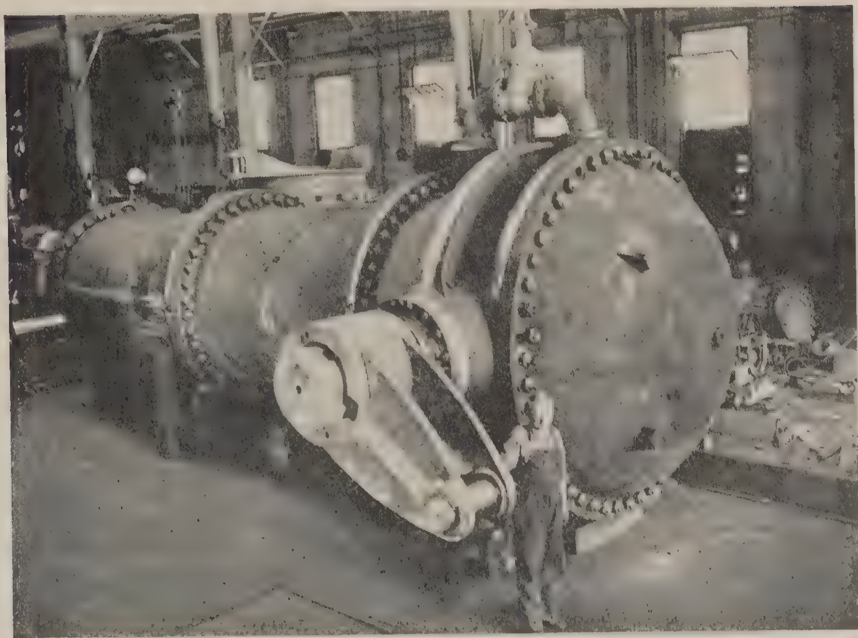

FIG. 7 ASSEMBLY VIEW OF TURBINE-SPIRAL CASING, INLET SECTION, AND BUTTERFLY VALVE AS ERECTED IN THE SHOP FOR TESTING

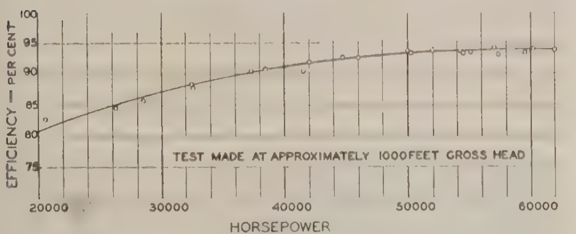

FIG. 8 RESULTS OF FIELD TESTS; MAXIMUM EFFICIENCY 93.7 PER CENT

Other results of field tests are as follows:

Gate opening required to bring unit up to speed, per cent	6.0
Pressure rise for full load off—148 ft or (per cent)	16.0
Speed rise for full load off, per cent	33.0
Power required to motor, runner submerged, kw	1750
Power required to motor, runner unwatered, kw	560
Wicket-gate leakage under full head, cfs	8.2
Oil pressure required to move gates, unwatered, psi	12
Oil pressure required to open gates, full head, psi	175

Gate leakage is sufficient to keep the unit running at 135 rpm before closing the butterfly valve but not sufficient to start unit from rest.

Following is a comparison of guaranteed, model, and field test efficiencies at 925 ft net head:

Per cent load	Efficiencies, per cent		
	Guaranteed	Model test	Field test
100	87.0	89.0	93.7
Best	89.5	89.5	93.7
75	88.5	86.6	93.0
50	84.0	79.0	88.0

Water Velocities. The following tabulation shows the approximate water velocities from the entrance to the butterfly valve to the discharge end of the draft tube, based upon the field test discharge of 610 cfs at rated load and head:

Location	Velocity, fps
Penstock	12.1
Butterfly valve	19.3
Casing entrance	23.5
Casing	29.8
Speed-ring discharge	49.5
Wicket gates	118.0
Entrance to runner, absolute	165.0
Entrance to runner, relative	38.0
Discharge from runner, absolute	37.0
Discharge from runner, relative	115.0
Draft tube, throat	31.2
Draft tube, bottom of cone	10.7
Draft tube, discharge passage	4.3

OPERATION

The turbine was placed in operation July 2, 1942. The field tests were made in August, 1942.

The operation of the Nantahala turbine is not unusual except for several operating limitations that are imposed due to certain design features that resulted from the high head. Some of the original limitations have been mitigated by slight changes in design and by the use of more suitable materials when repairs have been made. The remaining limitations as will be indicated do not impose any serious restrictions on the operation of this unit, in view of the fact that the Nantahala turbine is always operated as part of a large co-ordinated system in which it can normally serve as a base load plant.

The physical location of the powerhouse made a relatively long pipe line necessary between the surge tank and the unit. In order to protect this pipe line against excessive surge pressures it was felt desirable to provide relatively slow governor time. This slow governor timing makes it impossible to use the Nantahala unit for any tie-line load regulation which requires quick changes of load. The slow closing speed also results in an overspeed upon sudden loss of full load of approximately 33 per cent. Since the small load which would normally remain connected to this unit upon the loss of tie line can usually be taken care of by generation at smaller plants, it was considered very desirable to separate the Nantahala unit completely from the remainder of the system upon the sudden loss of load. To accomplish this an overspeed "inertia" relay was interlocked through a watt relay and con-

nected to trip the generator breaker immediately upon the occurrence of a fast rise in frequency, which would indicate loss of a major portion of the load. This relay installation effectively removes the unit from the system within $^1/_2$ sec and prevents excessive overspeeds on the small local system.

The runner of the Nantahala unit is partially submerged by the normal tail water, even when the unit is not in operation. This center line elevation was purposely selected in an effort to minimize cavitation of the runner during normal operation. This results in a positive pressure under the runner for loads up to approximately 57,500 hp at rated head, at which point the velocity head of the water and other disturbances create a negative pressure at the periphery of the draft-tube throat. It was found that when this negative pressure exceeds approximately 14 psi, cavitation noises start in the draft tube. Since the load at which this disturbance occurs varies with the gross head, a table has been prepared showing "maximum gate limit setting versus head," so that the wicket gates will not be opened beyond this critical setting. It has been found that the output varies from approximately 55,500 hp at the minimum head to 65,000 hp at the maximum head before these cavitation noises occur.

The setting of the runner below normal tail water makes it impossible to use the unit as a synchronous condenser without providing special features, such as compressed air to lower the tail water and to provide additional equipment to assure water lubrication to the seal rings during extended periods of operation as a synchronous condenser. After considerable discussion and investigation, this equipment was not considered justified due to the fact that the reactive kva can always be supplied from other units which are located closer to the load center.

A further limitation which was originally imposed on the operation of the machine was a precaution against operating for extended periods below one half rated load due to the excessive wear which would result from operation at light loads. This consideration is no longer as critical as it was originally due to the use of stainless steel in the repair of various of the wearing parts.

Maintenance

It was generally agreed, even before the turbine was installed, that considerable maintenance, particularly of the runner, would be required owing to the high head and high water velocities which exist in this unit. However, some additional problems were experienced which required some redesign as well as some repair.

As originally designed, an oil sump of 74-gal capacity was placed in a sector of the crown plate with the thought that sufficient cooling would be provided by contact of the underside of the oil sump with the water discharged through the turbine. This oil sump provided lubrication through one set of oil pumps to both the generator and turbine guide bearings. It was soon found that there was not sufficient heat transfer through the oil sump to cool the oil adequately, so a heat exchanger was inserted in the oil line between the oil pumps and the bearings.

The first difficulty with this system was experienced due to water spray from the shaft packing gland entering the oil system through the oil-collector pan underneath the turbine guide bearing. This water caused considerable rusting and pitting of the turbine-generator shaft just above the guide bearings, and also a rough rusty appearance on the actual bearing surfaces of the shaft. This condition was corrected by using a rust-inhibiting oil which was very effective in eliminating the rusting, pitting, and sludging which had taken place in the original oil. Admission of water into the system from the packing gland was later effectively eliminated by adding a water deflector to the shaft just above the packing gland, but moisture continued to be present due to condensation on the cool surfaces of the sump walls.

Although the location of the oil sump in the crown plate conserves space in the structural design of the powerhouse, it results in a very unsatisfactory location from a maintenance standpoint. It is practically impossible to clean out completely the sump and to remove all traces of moisture and sediment. In order to remove moisture of condensation effectively, a continuous small blotting-paper filter has been installed in series with the oil line.

It was also found that the one oil-pumping system would not satisfactorily lubricate both the turbine and the generator bearings. This was due to the fact that the generator bearing is located approximately $7^1/_2$ ft above the turbine bearing, and also to the fact that the generator bearing was supplied through a small orifice, whereas the turbine bearing was supplied through a $^3/_4$-in. pipe. Any small or slight obstruction in the generator piping orifice would merely force the oil into the turbine bearing without resulting in an appreciable rise in pressure to remove the obstruction. This combination system was separated to provide an independent forced oil lubrication system with separate oil sump and heat exchanger for the generator guide bearing.

Provision was made in the original design of the turbine for the runner to be removed by means of a cable through a hole in the generator shaft. The cable and runner could then be handled by means of the main powerhouse crane. However, the upper portion of the hole through the shaft was also used for the generator-field leads which extend from the field poles to the collector rings. Early experience indicated that considerable time and effort would be required to remove and reinstall the generator leads every time the runner was removed. It would also be difficult to keep the runner centered when it was being lifted by the cable due to the close seal-ring clearances. It was therefore decided to remove the runner by means of jack bolts and a special frame so that all of the work could be carried on from below the scroll case where the entire operation could be observed and closely checked by the maintenance force. It has been found that by use of this device, a runner can be removed and completely reinstalled by a six-man crew in five 8-hr work shifts.

Another small detail which developed was the fact that under certain conditions when filling the draft tube and scroll case, a water hammer was created which forced water up through the hole in the shaft and out into the generator rotor, and also into the main thrust-bearing oil sump. Since it was felt that the hole served a useful purpose of admitting air to the draft tube, this problem was corrected by installing a check valve at the lower end of the shaft in such a manner that air would be admitted through the shaft to the draft tube but water would be checked and prevented from rising up the shaft.

After the completion of the original installation it was noticed that the wicket gates would not completely pinch when closed against full water pressure. Upon release of the water pressure from the scroll case, the gates would move to the completely closed position. It was found that due to an unbalanced pressure under the gate stem, amounting to an upward thrust of several tons per gate, the upper flange of the crown plate against which the thrust collars pressed deflected sufficiently to allow the top of the gates to rub the upper wearing plate. This condition was corrected by readjusting the thrust collars on the stems and by installing lugs and additional bolts to minimize the deflection of this flange. Whereas it was originally necessary to close the butterfly valve in order to bring the unit completely to a stop, the unit can now be brought to a stop by merely closing the wicket gates.

The major portion of the maintenance and repair of the unit results from pitting and erosion that are caused by the high water velocities and pressures. Realizing that considerable maintenance would be necessary, frequent inspections were made of the unit after it was placed in service. After about 6 months of operation, the wicket gates and the back side of the nonoverlapping parts of the runner vanes began to show signs of erosion or pitting.

After a year's operation, the wearing plates opposite the top and bottom surfaces of the gates had started to erode, the seal-ring clearances had increased from 0.015 to 0.020 in., and considerable wiredrawing could be observed on the closure contact surfaces of the gates, despite the fact that the butterfly valve was always closed and pressure removed from the scroll case within a few minutes after the wicket gates were closed.

After two seasons of operation the Nantahala unit was dismantled with the intention of making minor adjustments and repairs, such as the welding in the field of small areas of the wicket gates, wearing plates and runner that showed wear from an inspection of the completely assembled machine. However, upon removal of the runner the complete extent of the wear could be observed, and it was evident that a major overhaul would be required. It was decided that the following parts should be renewed or repaired: runner and seal rings, throat ring below runner, wicket gates, curb and crown-plate wearing plates and rings.

The stainless steel originally applied to the ends of the wicket gates and the stainless seals used for the butterfly-valve seals showed no sign whatever of erosion or other damage. Fig. 9 shows a typical wicket gate before being repaired. The curb and crown-plate wearing rings and the seal rings on the runner had originally been made of S.A.E. 1045, a carbon-manganese steel, heat-treated to a Brinell hardness of 200 to 235. It was thought that this material would be suitable for resisting the erosion from the high velocities, but this was not the case. The stationary seal rings were made of cast steel, each with two bronze inserts held in place with calking strips. The bronze inserts eroded faster than the carbon-steel rings on the runner.

The parts to be restored were shipped back to the turbine manufacturer and were treated as follows:

The nonoverlapping back sides of the runner vanes and the inside of the runner band from the vanes to the bottom edge were recessed about $^1/_8$ in., overlaid with 25-20 stainless welding and refinished. The runner wearing rings were replaced with steel rings overlaid with 25-20 stainless-steel welding. It would have been less expensive to use stainless bar material for this purpose but necessary early delivery could not be obtained during the war.

Fig. 9 Typical Wicket Gate Before Being Repaired

The bore of the cast-steel throat ring for a distance of 6 in. from the top was similarly treated with a stainless overlay.

The bronze inserts in the stationary seal rings were replaced with inserts made of a 13 chrome-stainless steel. This gave two different grades of stainless steel working opposite each other so that even if they should accidentally touch in operation, galling would not result.

The entire downstream side and one third of the upstream side of the body of each forged-steel wicket gate were overlaid with 25-20 stainless welding and refinished. The intermediate and lower wicket-gate stem bearings which had pitted somewhat from corrosion were restored with a stainless metal-spray finish, and a collar was shrunk on the lower gate stem adjacent to the gate to help retain grease on the lower bearing surface.

The curb and crown-plate wearing plates and rings opposite the runner periphery were renewed with mild steel overlaid with 25-20 stainless welding. At the same time total clearance at the end of the wicket gates was reduced from 0.020 to 0.015 in.

In order to make the foregoing repairs the unit was taken out of service on March 6, 1944, and by working continuously it was put back into operation on May 2, 1944. No water was lost from the reservoir during the 56 days the unit was down.

As a result of the changes the power output was increased about 5 per cent, 3000 hp, because the runner-discharge openings were increased. The leakage through the runner seals was even less than when the unit was first installed. With the smaller wicket-gate clearance and complete closure of the gates, the unit would stop of its own accord with the gates closed and the butterfly valve left open, whereas previously it would not.

After two additional seasons of operation the runner was again removed for a detailed inspection of the unit. All of the stainless steel which had been properly applied was still in perfect condition. Even the tool and the file marks still showed, indicating that very little if any metal had been removed due to erosion or pitting. The closure contact surfaces of the wicket gates were also in perfect condition. A number of spots were found on which the stainless-steel weld had been almost completely removed when the piece was remachined and those spots were pitting or eroding appreciably. These small areas were chipped out and filled in with 18-8 stainless-steel rod; and subsequent inspection indicates that this work was very effective.

Evidence of the effectiveness of stainless steel was clearly demonstrated by surfaces of the stationary wearing ring which is installed in the crown plate opposite the periphery of the runner. Through an oversight in the repair work, an inside vertical surface of this ring was coated with $^1/_8$-in. stainless-steel overlay but the lower horizontal surface which adjoins the wearing plate was not coated except for the $^1/_8$ in. vertical overlay that extended to this lower horizontal surface. After two seasons of operation the mild steel between the wearing plate and the $^1/_8$-in. stainless-steel overlay was eroded or pitted to a depth of $^1/_{16}$ to $^3/_{32}$ in. This area was repaired in place by chipping out and filling in with stainless-steel welding rod.

After the runner was removed for this inspection it was decided to install the spare runner and to perform additional stainless-steel welding on the original runner to cover areas which were not repaired when the unit was returned to the factory. These areas consist primarily of the top and bottom edges of the periphery of the runner and a portion of the working face of the vanes where the water impinges upon starting. Considerable

erosion occurs on these faces because the runner acts as an impulse rather than a reaction wheel at small gate openings.

It was gratifying to note that even the seal rings did not show any wear. The manufacturer showed good judgment in applying different grades of stainless steel to the stationary and movable seal rings, since it was found that they had actually touched in a few spots without appreciable damage. It was found that the contact between the two surfaces was due to warpage of the inserts, which probably resulted from internal stresses which had not been relieved. This was corrected by grinding the stationary seal-ring inserts to a true circle by means of a field-constructed jig, and by buffing the movable rings. All of the surfaces were trued up and refinished without changing the original clearances appreciably.

The use of stainless steel has greatly reduced the amount of maintenance work which would have been required to keep the unit in a safe and efficient operating condition. By maintaining smooth surfaces it undoubtedly greatly increases the average long-term efficiency of the unit and removes some of the previous limitations that had been imposed to reduce wear on the unit.

Conclusion

During the more than 3 years' operation of this unit, all the difficulties encountered have been corrected. It is believed that the moderate initial cost (as compared with other types), the very high efficiency, and the absence of serious operating difficulties have amply justified the selection of the Francis type for the conditions under which this turbine operates, and that it will have a long life, with only moderate renewals and repairs.

Discussion

G. D. Johnson.[4] The use of Francis instead of impulse turbines under head of 1000 ft and over has again been vindicated by the Nantahala turbine.

Because of the high efficiencies attainable and the economies in first cost due to high-speed equipment with small space requirements for the amount of power developed, there is a natural inclination to use Francis turbines for higher and higher heads. However, because of operating difficulties experienced with previous high-head installations, there are today only a few Francis turbines in the entire world operating under heads approximating 1000 ft. Apparently use of stainless steel and improved welding techniques will now assure satisfactory, reliable operation of units of this type without excessive maintenance.

The writer was privileged to witness a vivid illustration of this modern trend, when in November, 1945, he visited the Lages Plant of the Rio de Janeiro Tramway, Light, and Power Company (The Light) in Brazil. At present this plant contains eight four-jet vertical-shaft impulse turbines and two vertical-shaft Francis turbines, all of European manufacture, operating under a rated head of 310 m (1018 ft). The small space occupied by the 50,000-hp 600-rpm Francis units, as compared with the size of the 9000-hp and 19,000-hp 300-rpm impulse units, was striking. Moreover, the maintenance on the Francis wheels, installed in 1940, and 1942, respectively, and equipped with special alloy-(stainless-) steel runners, has consisted mainly of stainless-steel welding on the gates and is no more than is required on the runners, needles, and nozzles of the impulse wheels. No erosion or cavitation of the runners was apparent after 3 to 5 years of service. This is due, of course, to the use of special material in the castings, but it is apparent that, as in the case of the Nantahala turbine, the liberal use of stainless steel results in units requiring a minimum of maintenance.

The writer congratulates the authors on the courage and skill demonstrated in the conception and design of the Nantahala turbine and on the success which they have achieved in its operation, as well as on the manner in which they have presented the complete story in their excellent paper. Their generous discussion of design considerations and operating experiences will undoubtedly promote further worth-while developments in the application of hydraulic turbines to high-head power generation.

S. J. Needs.[5] The paper was particularly interesting to the writer, who happened to be at Nantahala on several occasions while the machine was being installed. It is also timely in that it discusses a most unusual machine after it has been proved successful in service. Comparison with larger machines makes it difficult to realize that such a small turbine can develop so much power. Its high output is due, of course, to the exceedingly high head and this is one of the features which make the installation so outstanding.

The authors mention the spherical thrust bearing selected for this machine, and since the bearing is also quite unusual and interesting, a few words about it are in order. Instead of the flat thrust and cylindrical upper guide bearing, common in vertical machines of this type, a spherical thrust bearing is used. This bearing is capable of supporting radial as well as vertical loads, hence it eliminates the upper generator guide bearing.

The spherical thrust bearing for the Nantahala unit is shown in Fig. 10 of this discussion. It is located at the top of the machine and it runs in an oil bath with a cooler like most Kingsbury bearings in hydroelectric service. It is 51 in. diam and to date is the largest spherical bearing that has been built. The rubbing surface of the runner A is a zone of a sphere, the center of which is on the shaft axis. Six segmental spherical shoes B are fitted to the runner and pivoted in the usual Kingsbury manner. The bearing angle of the shoes is 39 deg with respect to the shaft center line. Total vertical thrust load is 575,000 lb or about 96,000 lb per shoe. Due to the bearing angle the normal load per shoe is about 123,000 lb and its horizontal component is approximately 78,000 lb. The shaft is held concentrically by the horizontal components of the thrust load acting radially at each shoe. The babbitt surface area of each shoe is 261 sq in. and loading per unit area is 472 psi.

At the normal operating speed of 450 rpm the average minimum film thickness along the trailing edges of the shoes is 0.0026 in. under the loading cited. When a horizontal load comes on the bearing the shaft can move sidewise due to the slight decrease in oil-film thickness at the more heavily loaded shoes. A side load of 10 per cent of the vertical thrust will decrease the minimum film thickness 0.0004 in., or 15 per cent. Twenty per cent side load will decrease the minimum film thickness 0.0006 in. or 24 per cent, and 40 per cent side load will cause the normal minimum film thickness to decrease somewhat less than 0.001 in. or about 36 per cent. Sidewise movement of the shaft is approximately the same as the change in minimum film thickness, from which it follows that the shaft is held very close to a central running position, even under appreciable side loads.

Total frictional power loss at full load and speed due to oil-film shear is 175 hp. This is about the same as the combined frictions of the corresponding flat thrust and cylindrical guide bearings. The frictional heat is removed by a cooling coil consisting of approximately 1000 ft of $1^1/_8$-in-diam copper tubing. Oil is circulated around the cooler by means of a centrifugal pump consisting merely of two opposite holes drilled in the runner at an angle. At 450 rpm the peripheral speed of the

[4] Hydraulic Engineer, S. Morgan Smith Co., York, Pa. Mem. A.S.M.E.

[5] Service Manager, Kingsbury Machine Works, Philadelphia, Pa. Mem. A.S.M.E.

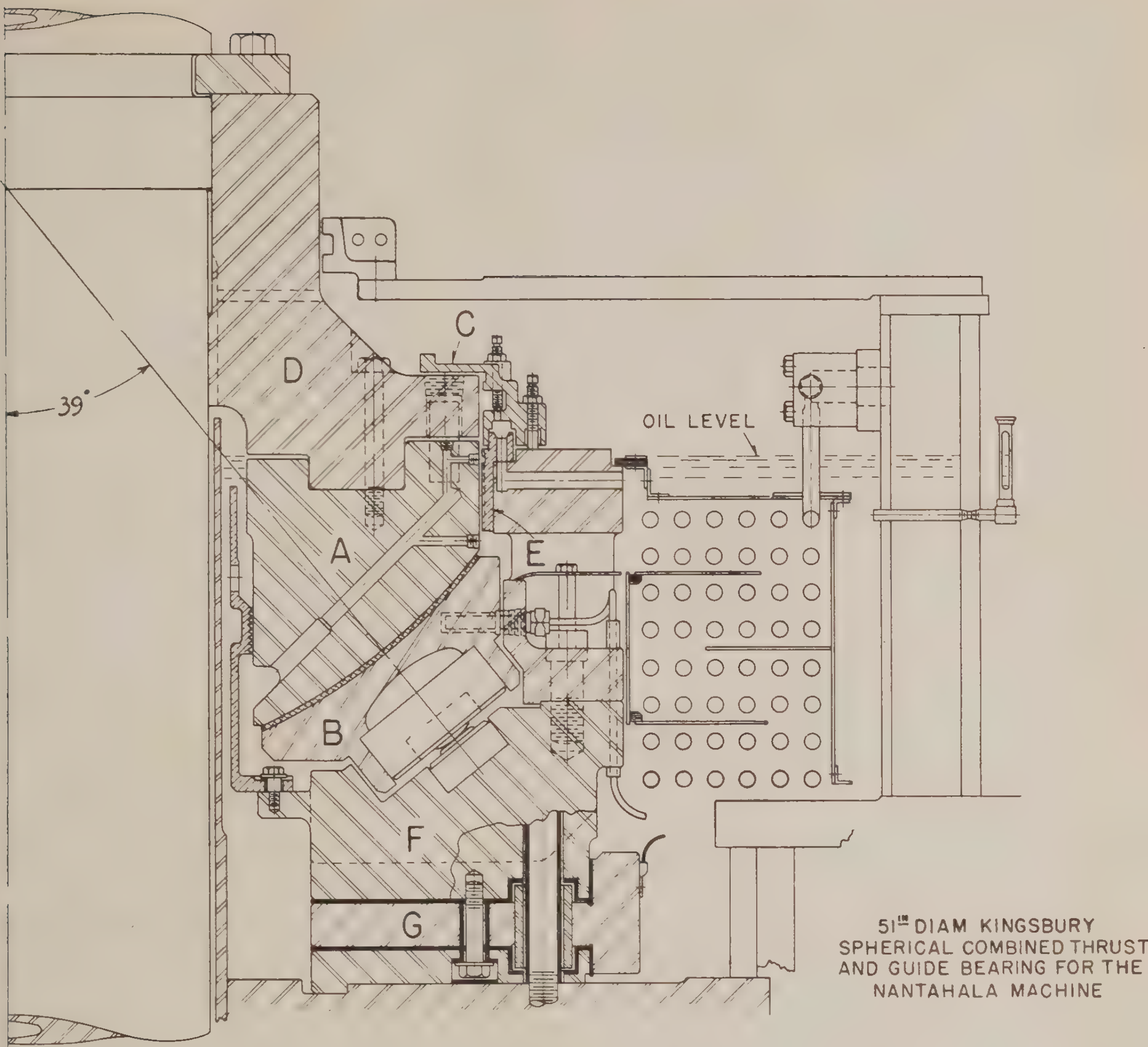

Fig. 10 Spherical Combined Thrust and Guide Bearing for the Nantahala Machine; 51 In. Diam

runner is 101 fps or about 69 mph. Static pressure at the discharge ends of the pumping holes is 43 psi and about 35 gpm is circulated around the cooler tubes. This flow is increased by the centrifugal action of the runner surface on the oil in the spaces between the shoes.

Clearance between the air-seal ring *C* and the removable thrust block *D* is so adjusted that oil is maintained in this space, thus sealing the bath against entrance of air. The inner air-seal ring at the runner bore prevents air from entering the oil at that point. Due to these seal rings the top of the bath is clear and practically motionless.

In the unlikely event that the shaft should ever rise, a cylindrical bronze guide bearing *E* is provided. Radial clearance between the outside diameter of the thrust runner and the guide bearing is $^1/_{16}$ in., hence this emergency bearing is practically frictionless in normal operation.

Beneath the solid base ring *F* the bearing is provided with double insulation against shaft currents. A lead from the interbase *G* makes it possible to test the insulation at any time.

The principal advantages claimed for the spherical thrust bearing are as follows:

1 The shaft is held in a concentric running position as if in a guide bearing of zero clearance.

2 Any inaccuracies of the thrust block and ring key are compensated for by the permissible rolling action of the spherical runner. Movement so induced at right angles to the direction of motion would be of small amplitude and practically unresisted by the fluid oil film. Hence galling between thrust block and shaft and shaft throwout at the turbine bearing due to thrust-block inaccuracies are eliminated.

3 The spherical bearing simplifies design of the thrust bracket by eliminating the cylindrical upper generator guide bearing and the special oil pump and piping usually required for its lubrication.

4 The spherical bearing is so constructed that at zero speed the babbitt faces of the shoes are segments of a true spherical zone and will bear equally against the runner. Thus equal shoe

loading is inherent, no field adjustments of loading are necessary.

5 The vertical center lines of bearing and shaft will intersect at the center of the runner sphere, but it is not essential that these center lines coincide. Hence equal shoe loading will obtain despite shifting of foundations and appreciable departure of the shaft from plumb. To obtain this self-alignment with a flat bearing requires the use of leveling-plate equalizing construction.

J. F. Roberts.[6] This 60,000-hp Francis-type turbine, operating under 925 ft net head, has set a new mark in American practice for high-head reaction-type turbines.

One point which strikes us as particularly important is the marked improvement which stainless steel shows as compared with either cast steel or rolled steel in resisting cavitation and scour erosion due to the high velocities under these relatively high heads. This further confirms data gathered in regard to cavitation of Kaplan and propeller-type wheels. Possibly the Europeans are right in their conclusions that it is well worth while to make the runners and some other vital parts entirely of stainless steel. In this particular case, had the runner, guide vanes, and facing plates been made of stainless steel, possibly all of the repairs required at the end of 2 years of operation might have been avoided. Until recently it has been impossible to secure a stainless-steel runner in this country, but during the war several of the steel foundries have enlarged their stainless-steel casting capacity and several stainless-steel runners are now being manufactured. It will be interesting to see whether or not these outlast their carbon-steel predecessors.

The fact that stainless steel was used in the butterfly valve both as the seal ring on the disk and seat in the housing with excellent results further confirms the data regarding its greater resistance to wear and erosion. While discussing the butterfly valve, the excellent streamlining on the downstream side of the disk so as to maintain practically uniform velocity as the water flows from the valve into the spiral casing deserves mention. The housing contracts rapidly so that there is no decrease in velocity as the water leaves the area surrounding the disk, which in this case probably occupies from 25 to 30 per cent of the effective area in the valve.

The company with which the writer is connected built a 30,000-hp impulse turbine of the double-overhung type for this same power company at about the time the Nantahala turbine was built. The difference in efficiency of an impulse turbine as compared with the reaction turbine was more than expected. While the impulse turbine gave about 1 per cent higher than the expected 88 per cent, or about 89 per cent, it still was over $4^1/_2$ per cent below the 93.7 per cent obtained on the Nantahala turbine. Mr. Growdon and the other officials of the Nantahala Power Company, in discussing this difference, agree with the writer that if we had had as much experience with high-head reaction turbines at the time of building these plants, both plants, that is, Glenville as well as Nantahala would have been of the high-head reaction type.

The tabulation showing the comparison in efficiency between the 22-in. model and the 85-in. Nantahala turbine deserves consideration, especially the increase of 9 per cent at half load from the model to the full-sized unit in the field. This is also one of the rare cases where the actual field tests showed a greater improvement in the plant than is indicated by the Moody formula, as the Moody formula would show only about 92.5 per cent efficiency as compared with the 93.7 per cent actually obtained.

While the Nantahala turbine is set with the center line of the spiral casing about 4 ft below the average tail water, the fact that serious cavitation noises occurred at loads slightly below rated capacity indicates the desirability of setting this type of turbine even lower in order to decrease such cavitation. Had this turbine been set some 4 or 5 ft lower than it actually was, we feel that the cavitation limit would have been materially improved, that is, larger capacity would be possible without cavitation noises and, undoubtedly, considerably less pitting and erosion would have shown up on the runner.

The authors are to be complimented on the frankness of their discussion in placing this valuable information before the Society. There is no doubt that this paper will be beneficial to many other prospective users of this specialized type of hydraulic equipment.

F. H. Rogers.[7] This paper is of great interest to both the operating companies and the turbine manufacturers as the use of Francis turbines for heads of about 1000 ft is exceptional. The authors are to be congratulated on the frank description of the original difficulties experienced and the corrective methods used. The maximum efficiency obtained of 93.7 per cent is indeed a splendid record.

As pointed out in the paper, the successful use of a Francis-type unit instead of the impulse type results in higher efficiency, higher speed, and lower cost. The difficulties to be guarded against are unstable operation, pitting due to cavitation, and wear of internal parts, caused by the extremely high velocities and abrasive materials in the water, and loss of the original efficiencies due to wear at the runner seals.

An interesting comparison with the Nantahala turbine is the 39,000-hp unit built by the writer's company for the Ixtapantongo Development of the Comision Federal de Electricidad in Mexico. This unit was designed for a net head of 1028 ft at a speed of 600 rpm. The specific speed is 20.3, only slightly less than the value of 21.6 given in the paper.

In the Nantahala unit a radial clearance of about 6 in. was allowed between the wicket gates and entrance to the runner vanes to result in smooth flow from the gates into the runner. For the Ixtapantongo unit the corresponding clearance was about $2^1/_2$ in. It is our experience that so large clearance is not necessary if wicket gates are so streamlined as to produce smooth flow. This smaller clearance results in decreased size of unit and lower cost.

The authors describe how the heavy upward hydraulic thrust on the bottom of the gate stems caused a deflection of the upper flange of the crown plate, which permitted the top of the gates to rub the upper wearing plate, and this friction prevented sufficient gate closure to stop the turbine completely.

This difficulty was avoided in the Ixtapantongo unit by extending the lower gate stems through stuffing boxes in the lower cover, thus eliminating all upward thrust.

The repairs made after 2 years of operation are of particular interest. It is noted that considerable wear occurred on the runner, throat ring, gates, curb, and crown-plate wearing rings and seal rings, and that these parts were repaired by welding the surfaces with 25-20 stainless-steel rods.

In the case of the Ixtapantongo unit, the same carbon-manganese steel (S.A.E. 1045) was used for the wearing rings and seal rings, and the same bronze inserts in the stationary seal rings. This unit, however, has been in operation only about 18 months, but the power company reported that an inspection made after the first year of operation showed no appreciable pitting or wear of the internal parts.

The authors speak of erosion or mechanical wear rather than pitting and the writer would like to know if this wear was caused by erosive action from sand or other abrasive materials in the water. It is noted that water is carried through an unlined pres-

[6] Manager, Hydraulic Department, Allis Chalmers Manufacturing Company, Milwaukee, Wis. Mem. A.S.M.E.

[7] Manager, Hydraulic Turbine Sales, Baldwin Locomotive Works, Philadelphia, Pa. Mem. A.S.M.E.

sure tunnel, which might result in foreign materials being present in the water.

It has been our practice to use 18-8 stainless steel on the runner vanes, gates, wearing rings- and seal rings to resist pitting rather than the higher chrome-nickel materials. We understand that recent tests made at the Massachusetts Institute of Technology indicated that a 17-7 stainless steel showed greater resistance to pitting than the higher combination of chrome and nickel.

It is quite possible that the 25-20 stainless steel used at Nantahala has a higher Brinell hardness and will stand up better where sand is present under these extremely high velocities. We would like to have the authors' opinions on this matter.

The efficiencies obtained on the field test as compared to the model test are unusual, as at best efficiency the prototype shows 93.7 per cent and the model 89.5 per cent; a gain of 4.2 per cent. The well-known Moody formula[8] would show for the runner sizes and heads stated, a gain of $3^1/_4$ per cent for a coefficient of $n = 0.25$, and a gain of $2^3/_4$ per cent for a coefficient of $n = 0.20$. The gain at part loads of 6 to 9 per cent over the model efficiencies is even more unusual, as such gains are rarely higher than at the maximum efficiency. Our company is of the opinion that the exponent $n = 0.25$ results in too high an efficiency for the prototype and is now using the value $n = 0.20$.

R. E. B. Sharp.[9] An efficiency of 93.7 per cent with a specific speed of 21.6 represents an important advance in hydraulic-turbine performance. Surrounding conditions, justifying large units of the Nantahala characteristics are rare, and unfortunately the conducting of field tests of such units is even rarer.

It is gratifying for those interested that the Aluminum Company has seen fit to test not only the Nantahala unit, but also four of the Shipshaw units as well, three Allis-Chalmers, and one S. Morgan Smith, with water measurements by the Gibson method and all with excellent efficiencies. The Smith unit attained a maximum efficiency of 93.6 per cent and was one of four built by S. Morgan Smith, Canada, Ltd.

The Ixtapantongo unit, which was designed under the writer's direction and built by The Baldwin Locomotive Works for the Comision Federal Electricidad of Mexico, has, regrettably, not been field-tested. This unit is also of the Francis type, with a rating of 39,000 hp under a net head of 1028 feet, with a specific speed at rated power of 21.8. It was put into operation during the summer of 1944, and therefore does not have as long a case history as the Nantahala unit.

In an effort to predict, on the basis of the Nantahala performance, the maximum efficiency which might be attained from a runner of still lower specific speed, the writer, in Table 1 of this discussion, has made a comparison of those estimated losses which vary most greatly with specific speed.

The disk losses include only the external runner surfaces, both of the crown and band. The Unwin formula

$$2.07 \times 10^{-10} \times \text{rpm}^3 \times \text{diam in ft}^5$$

was used. For the surfaces which depart from a disk shape a

TABLE 1 COMPARISON OF ESTIMATED PERFORMANCE OF VARIOUS HYDRAULIC-TURBINE RUNNERS

	Shipshaw	Nantahala	Hypothetical unit
Specific speed at best efficiency	44.3	21.6	15

	2.664	2.536	4.147

summation of small divisions was made. The clearance losses were obtained by determining the velocity head at the seals and deducting this from the head acting, using a coefficient of 0.5 through the area and allowing for the reduced head on the seals due to the centrifugal effect between the runner periphery and the seal location. The authors may be able to state the measured Nantahala clearance loss. The draft-tube losses were calculated assuming a draft-tube efficiency in all cases of 80 per cent. The shock losses are on the assumption that one tenth of the radial velocity head entering the runner is lost. All losses were calculated at best efficiency. While the aggregate losses not included in this comparison amount to more than the sums of those included, it is believed that this comparison gives a fair indication of what efficiency might be expected from a Francis turbine of still lower specific speed for possible use with an appreciably greater head than 1000 ft, that is, something over 92 per cent for such conditions would be in order with a runner of about 85 in. diam. An account[10] has been given of a unit of Escher Wyss design which attained from field test an efficiency of 91.4 per cent when developing 16,000 hp under a head of 918 ft, at a specific speed of 15.07. The diameter of this runner was only 70 in.

The introduction of 80 gpm of clear water into the seals is an interesting feature, but the small amount used leads the writer to question the advantage gained thereby as a means of protecting the seal rings from the passage of foreign matter. Possibly the original reason for the introduction of this water was in connection with synchronous-condenser operation.

One of the principal advantages in obtaining well-conducted field tests, to the turbine designer, is the comparison thereof with the model performance, as this is the yardstick for use in future guarantees and designs. The Nantahala field test is unusual in that the step up in efficiency is so great. The Moody formula on the basis of the losses varying inversely with the one-fourth root of the runner diameters would result in a field efficiency of 92.5 per cent. A field efficiency of 93.7 per cent corresponds with an exponent of about $\frac{1}{2.6}$. Possibly one reason for the large increase might be in the relatively large model seal clearance. For this value to be homologous on the model it would be

$$0.015 \times \frac{22}{85} = 0.0039 \text{ in.}$$

which is an impracticably small value.

On the lower portion of Fig. 11 of this discussion is shown the model curve as compared with the field, as plotted from the data in the authors' paper. It is noted that the guarantees at part load are disproportionately higher than the model curve which falls off quite rapidly. Further information in regard to this point would be of interest.

On the upper part of Fig. 11 a comparison is given of the Shipshaw field and model tests of the Smith unit tested. In this

[8] Moody formula:

$$E_p = 100 - (100 - E_m)\left(\frac{D_m}{D_p}\right)^n \times \left(\frac{H_m}{H_p}\right)^{0.01}$$

where

E_p = efficiency of prototype
E_m = efficiency of model
D_p = runner diameter prototype
D_m = runner diameter model
H_p = effective head on prototype
H_m = effective head on model

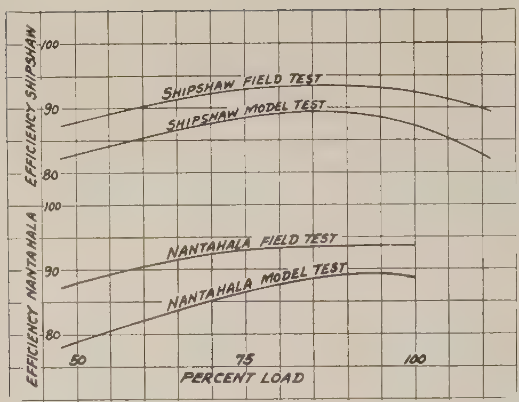

Fig. 11 Efficiency Curves of Model and Field Tests of Nantahala and Shipshaw Turbines

instance the 19.5-in-diam model attained 89.6 per cent efficiency. The Moody formula steps this up to 93.8 per cent field efficiency, which agrees quite closely with the actual value of 93.6 per cent. Both the Shipshaw and Nantahala field tests show satisfactorily high part-load efficiencies, with the Nantahala values somewhat higher if they are both brought to the same percentage of load for maximum efficiency.

The authors make no mention of presence or absence of foreign matter in the water, but it would appear that there is some abrasive matter present, and possibly some degree of acid content. The writer had occasion to examine the seals of Units N5 or N6 at Boulder after about a year of operation under a head above 500 ft, and found the clearances on the average slightly less than when the units were installed, due to the deposit, in some places, of verdigris on the white brass inserts in the stationary rings. The Boulder water was, during this period, exceptionally free from abrasive matter.

The substitution on the Nantahala turbine, of stainless steel on the stationary wearing ring for bronze, while showing gratifying results from the standpoint of maintained low leakage loss, appears questionable to the writer from the standpoint of safety during possible runaway speed. Assuming a runaway speed of 725 rpm, which is believed to be conservative, calculations made indicate an expansion at this speed of about 0.008 in. on the radius, leaving 0.008 in. as the clearance under that condition or a possibility of this being reduced to 0.003 in. if the shaft swings to its extreme position in the bearing. Even though the rotating and stationary seal surfaces are not subject to galling, the presence of two broad surfaces of hard metals under this admittedly abnormal condition might result in violent seizure due to heating after contact. In view of the excellent resistance of stainless steel for these surfaces, as brought out by the authors, labyrinth seals of this metal along the lines used in steam-turbine design might be a good solution from all standpoints.

On the Ixtapantongo unit mentioned the lower gate stems extended through stuffing boxes in the bottom, or curb plate, and were of the same diameter as the upper stems. This was for the purpose of avoiding the heavy upward thrust on the stems, and also of avoiding the loss of grease due to water passing under the lower ends of the stems and forcing the grease upward on the sides of the stems nearest the runner.

The writer wishes to congratulate Mr. Terry on the excellent design and performance of the Nantahala turbine, and all of the authors on the frank manner in which they discuss the difficulties encountered. This attitude is of distinct long-range benefit both to manufacturers and users.

Authors' Closure

The extent and quality of each of the several discussions is greatly appreciated by the authors. These discussions add greatly to the value of the paper.

While the spherical Kingsbury thrust bearing is installed on the generator, it is of course an essential part of the turbine as well. Mr. Needs's description of the design and construction of this bearing is most interesting and timely. So far, the bearing has functioned perfectly and we would definitely favor its use for hydroelectric units.

Mr. Roberts has misinterpreted the statement in the paper with respect to cavitation noises in the draft tube, since these noises only occur at loads above rather than slightly below the rated load for the various heads. The turbine operates regularly at between 45,000 and 46,000 kw under a net head of 951 ft without cavitation noises in the draft tube.

Several of the discussers raised questions relative to the presence of abrasive materials or acid in the water. The tunnel is driven through hard insoluble Arkose rock. It is unlined except near the portals. It was thoroughly cleaned and washed out before being filled. The washing removed most of the rock dust and small gritty particles. Some rock dust remained and was taken out by the water during the first few hours of operation. The water velocity in the unlined section of the tunnel at full load is approximately 4.75 fps, which is insufficient to transport loose material through the tunnel. Practically no rocks or sand have been found in the rock catcher, which is located at the end of the unlined tunnel just before the water enters the steel penstock. Except for the first few hours of operation, we believe that no sand or rock dust has passed through the turbine.

The drainage area is generally heavily wooded, with oak trees predominating. The water from this drainage area is therefore slightly acid. It does not affect the rate of corrosion.

The runner seal-ring clearances for the turbine model were 0.008 in., or relatively twice as large as for the main unit, which partly accounts for the large step up in efficiency, particularly at the lower percentages of output.

While the bulk of the welding with stainless was done with a 25-20 rod, some repair work was done in the field using 18–8 and 17–7 rods. These three grades of stainless rods have apparently stood up equally well in the field. 25–20 was selected because of the manufacturer's experience with the application of this grade. The resulting deposit, is, of course, diluted by the parent metal in any case, dilution varying somewhat with welding technique. The 25–20 rod is quite readily applied, and the resulting weld is somewhat more ductile than the other two.

The 80 gpm of cooling water supply to the runner seal rings was intended for use if the unit was operated as a synchronous condenser and not for the exclusion of any foreign matter. The unit is not, however, used as a synchronous condenser but the operators make a practice of turning on the seal water just before starting the machine. The supply valves are left open as long as the unit is in operation. The actual necessity for this procedure is questionable but it is certainly on the safe side. The seal supply pressure is limited. Consequently, the supply line is provided with a check valve to keep the water from backing up in the line as the turbine wicket gates are opened and the pressure builds up in the seal spaces.

The Ixtapantongo unit described by Mr. Rogers is of considerable interest. Experience with that unit for the first year closely parallels that of the Nantahala Unit. It was only after two years of operation at Nantahala that the extent of the wear with the carbon steel was appreciated. In other words, carbon steel stands up satisfactorily under this head for a limited time but it is the authors' opinion that stainless is needed for long-time trouble-free service.

New Developments in Combination Controls

By J. W. Kelly,[1] Burbank, Calif.

This paper deals with combination controls, which present advantages of weight and cost saving which in recent years have been greatly enhanced by the dependability and ruggedness which can be built into them. Small electric motors, developed for aircraft-accessory operation, have permitted the construction of motor-operated valves. Both solenoid- and motor-operated valves now give the aircraft designer a wide choice of control characteristics. New methods and improvements in older types of follow-up systems for hydraulic controls are discussed in the paper.

Introduction

COMPETITION between mechanical, hydraulic, and electrical modes of actuation has, through the last few years in the aircraft industry, produced certain results that would probably not have been obtainable otherwise.

After maximum efficiency with minimum weight had been obtained from each separately, it became obvious that combinations of the mechanical, hydraulic, and electrical systems, utilizing the best of each, would produce results heretofore unobtainable.

Hydronic Units

Realizing this condition, the author's company undertook a program several years ago of developing what we term "hydronic" controls (hydraulic-electrical combinations) and various mechanical-hydraulic combinations.

Solenoid Valves. The first of the hydronic units (the electrical-hydraulic combination) to be developed were the solenoid-operated selector valves. The field of available solenoids was thoroughly covered for possible standard units usable to operate selector valves. Unfortunately, none was found that came within our weight expectations; therefore a series of developmental solenoids were made. The results of tests on these solenoids set up the general type of solenoid to be used for valve actuation. One of the first solenoids put into production is the one shown in Fig. 1, which, with a weight of 21 oz, gives a pull of 60 lb over a stroke of $^1/_8$ in. at 18 volts. This solenoid was designed for intermittent operation and would reach a maximum temperature of 250 F after several hours of continuous operation.

Still not satisfied with the original solenoids, attempts were made to reduce the weight further. Finally a double-coil arrangement was worked out with a primary and secondary coil. When the solenoid is first energized, both coils contribute to the pull. The plunger, upon reaching the end of the stroke, operates a switch as shown in Fig. 2, interrupting the current to the primary coil, allowing the secondary coil to apply a holding pull. Thus an instantaneous high-amperage input operates the valve; and the secondary coil, with low-amperage input, taking advantage of the principle that pull increases inversely to the air gap, holds the valve in the desired position. This type of solenoid gives an exceedingly high pull with a minimum of weight.

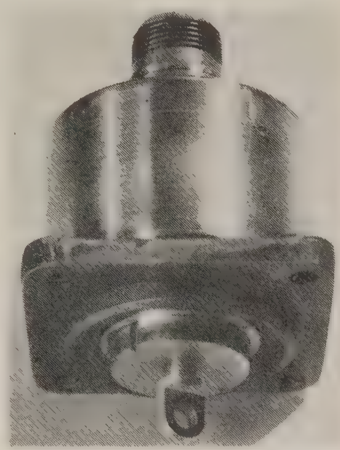

Fig. 1 First Solenoid Design; Weight 21 Oz

Fig. 2 Improved Solenoid Design; Weight 15 Oz

Having developed a suitable solenoid, a valve had to be designed to utilize the high-pull and short-stroke characteristics of the solenoid. One of the first solenoid valves built by the company used a rocker arm but did not require a neutral position. A 30-lb spring loads the rocker arm in one direction; the solenoid pulls 60 lb, thus 30 lb is available in both directions.

Fig. 3 indicates a valve having a rocker arm operated by dual

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

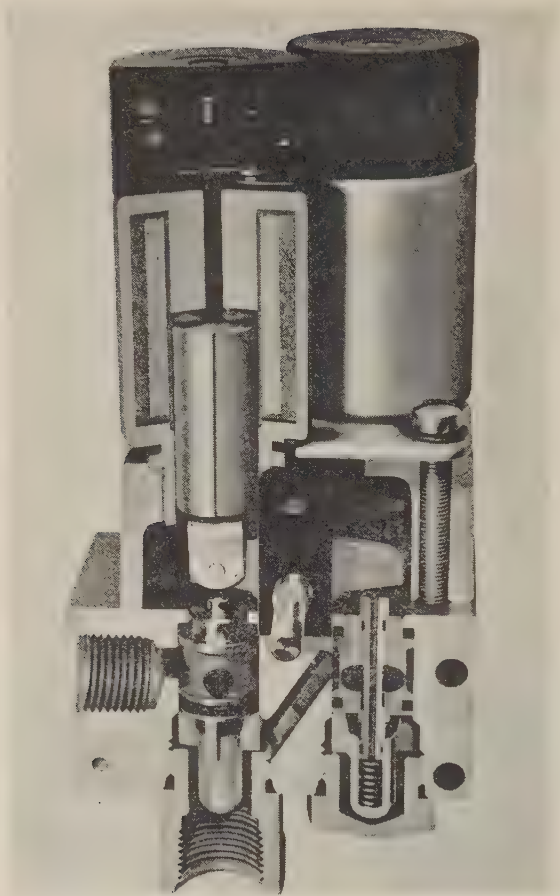

Fig. 3 Solenoid-Operated Selector Valve, Incorporating Rocker Arm

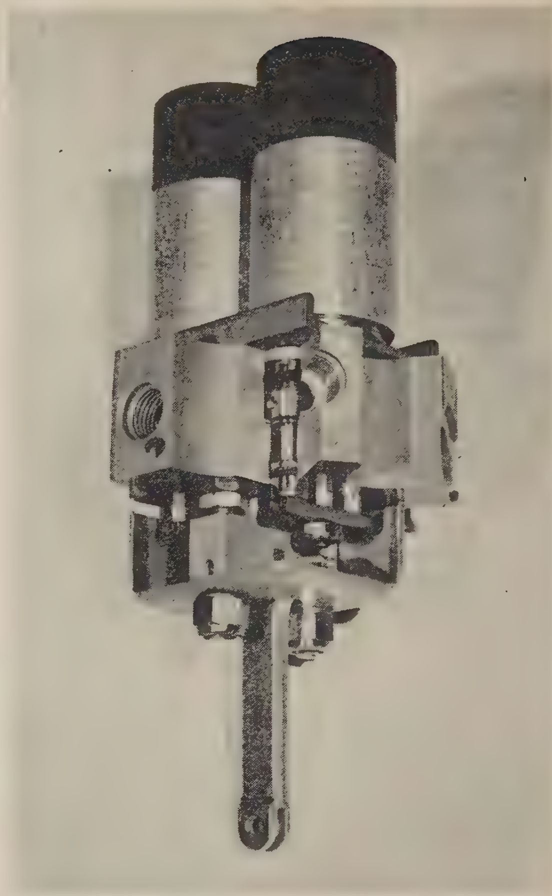

Fig. 4 Solenoid-Operated Selector Valve; Crossbar Replaces Rocker Arm

solenoids. This valve requires a neutral position; therefore two of the double-coil solenoids are utilized with one solenoid being energized for one position and the other solenoid for the other position. When neither is energized the valve is in neutral. On this valve an emergency override lever is added to allow for mechanical actuation in case of electrical failure.

In order to simplify design, over-all cost, and weight, a third type of actuation, as in Fig. 4, was developed which eliminated the need for a rocker arm. Because of the pressure and return-poppet arrangement it is possible to get a 4-way-valve action by lifting two adjacent poppets at a time; thus as shown in this illustration, a crossbar is put between these two adjacent poppets with the solenoid pulling on this crossbar. On this type of design manual actuation is easily provided.

Various types of valves for operating pressures of 1500 and in some cases 3000 psi, including the shutoff, 3-way and 4-way, have been designed for solenoid actuation having single solenoids, utilizing spring returns or double solenoids with and without rocker arm.

Electric-Motor-Actuated Valves. The advent of small inexpensive electric motors allows motor-operated valves to become competitive with solenoid-operated valves. Although the cost of the motor-operated valve is slightly higher at present, proper production engineering on either motor or solenoid valves may give either the cost advantage. Over and above cost consideration, performance requirements may dictate the use of either mode of actuation in that both have advantageous characteristics for particular applications.

Solenoid actuation has the advantage over motor actuation in conventional selector valves requiring a neutral position. Limit switches are required to obtain a neutral position in motor-operated valves; whereas, it is a natural function with solenoid-operated valves. Obviously, this advantage is lost to solenoid actuation on valves requiring no neutral position.

Emergency manual override is easier to obtain on the solenoid-operated valves, due to the free movement allowed in a solenoid when the current is not energized. A manual override on a motor valve leads to complications in design. Solenoid valves have the advantage where fast actuation is required, operating in a fraction of a second, whereas the time of motor-operated valves is usually measured in seconds. This applies, however, to direct-connected conventional poppet-design solenoid valves and not to pilot-operated valves which are inclined to be somewhat slow and erratic in operation.

Extremely high starting loads, usually obtained in the larger valves, are handled more effectively by motors which give out high initial torque as against the low initial torque of a solenoid.

A motor-operated valve can be readily designed to stay in

either extreme position without being energized, whereas a solenoid requires continuous energizing to hold its position, unless locking mechanism is provided.

In the weight-comparison graph shown in Fig. 5, solenoid valves are seen to be lighter in the smaller sizes than motor-operated valves, with the lines crossing slightly above the $^1/_2$-in-size valves. Above $^1/_2$-in-line size, the motor-operated valves have definite weight advantages.

Power Package. The power package, a combination of electrical and hydraulic units, has provided the industry with another unit of extreme versatility with weight saving. Several years ago, when the need presented itself for a valve actuator required to hold the valve in extreme positions for a protracted period of time, the device shown in Fig. 6 was developed. An electrical-mechanical actuator, originally contemplated, presented overheating problems when held in a stalled position. By utilizing a small electric-driven gear pump, taking fluid from the return side of the valve, a simple reversible pump-and-cylinder combination was worked out, providing easy actuation of the valve with a minimum of weight. No overheating problems were present due to the built-in leakage in the gear pump and the cylinder.

This device led to the development of a power package for actuation of landing gears and flaps for light aircraft. This unit combines a motor-driven gear pump, submerged in the hydraulic reservoir; the reservoir is surrounded by a glass tube, allowing visual inspection; an integral selector valve allows positioning; by-pass valve avoids any possibility of overflowing the reservoir; and a built-in relief provides adequate thermal protection. This unit weighing $4^3/_4$ lb, dry, has an output of $^1/_2$ gpm at 300 psi operating pressure.

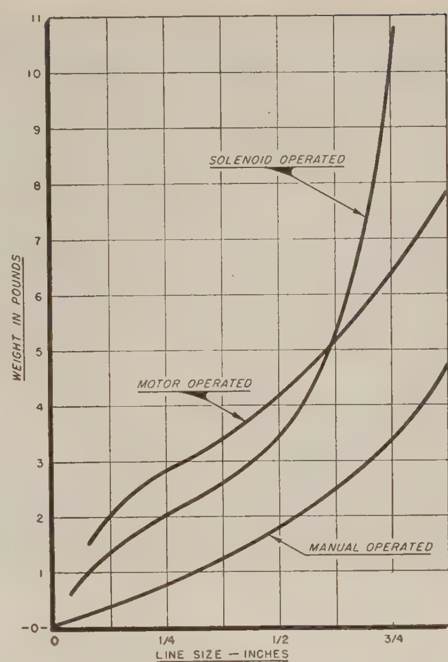

Fig. 5 Relative Weights
(Manual, solenoid- and motor-operated 4-way selector valves.)

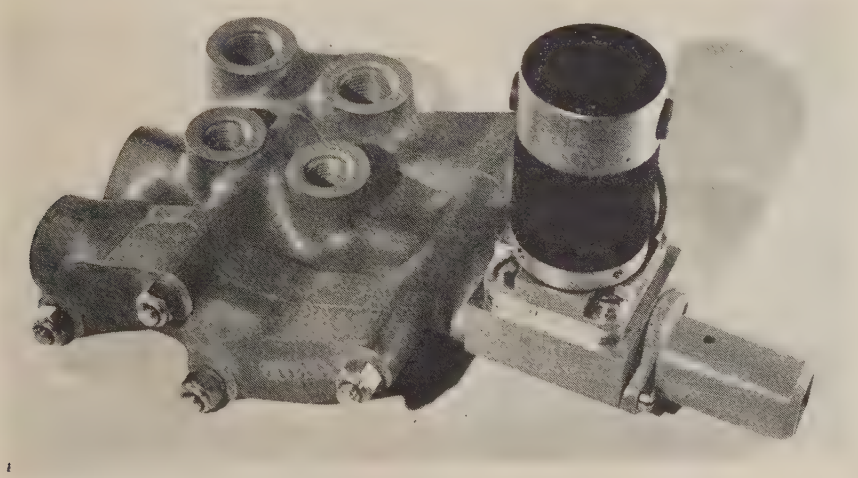

Fig. 6 Electrical-Hydraulic Actuator

Later requirements for a heavier-duty unit dictated a slightly sturdier design as shown in Fig. 7. Designed primarily for emergency power stand-by, it incorporates a motor, pump, reservoir, relief, and pressure and return ports. The glass-reservoir cover is replaced by a casting, with fluid level being easily determined by the use of a dip stick. Provision is made for the adaptation of the Adel Stacking Midget[2] (a manifold-type selector valve), thus a package unit can be obtained incorporating a motor, pump, reservoir, relief valve, auxiliary pressure and return ports, and/or 1, 2, 3 or more selector valves. This unit gives 800-psi output at 0.7 gpm with $^1/_3$ gal capacity for 11 lb weight, dry.

Another problem, somewhat different from the others, led to the development of the pump-and-tank combination which forms the basis of a power package. Difficulties in pumping oil at 35,000 to 40,000 ft altitude led to this particular pump design, which shows no cavitation effects at high altitude under high- or low-temperature conditions. The unit has a pump, motor, reservoir, with a built-in relief; selector valve, and other hydraulic components can be added to produce a power package which gives 6-gpm flow at 1000 psi with a weight of 37 lb. The

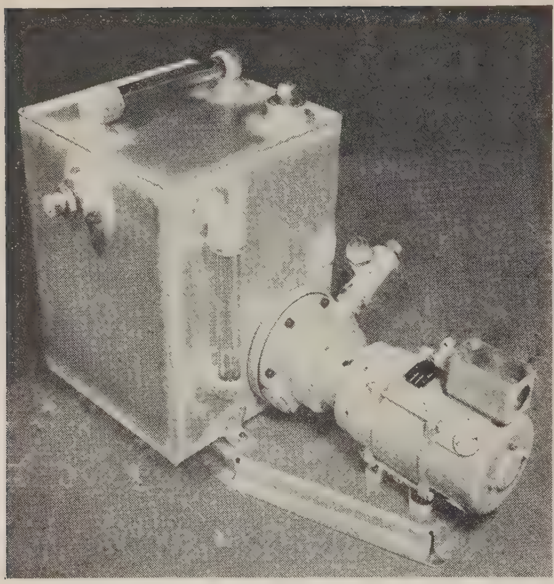

Fig. 7 High-Altitude Pump

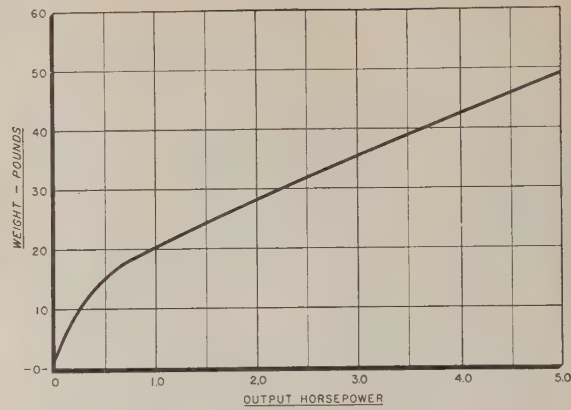

Fig. 8 Weight of Electrohydraulic Power Packages at Various Horsepowers

weights of the power packages are plotted against output hydraulic horsepower in the curve, Fig. 8. It is interesting to note the slope in the horsepower ratings below the 1-hp point.

Power Position Controls

The need for combination controls is definitely brought out in the field of the power position control. Utilizing hydraulic power as the desirable power source, three different types of follow-up systems which allow the utilization of efficient power position control will be discussed.

Mechanical Follow-Up. A simple mechanical follow-up system applied to hydraulic 4-way valves is shown in Fig. 9. We have developed several planetary-gear follow-up systems; but find that this walking-beam system, through sheer simplicity, has much to offer. The walking beam provides a simple follow-up mechanism on a sensitive rocker-arm-type selector valve. Movement of the master or control lever, opens the valve which in turn operates the power cylinder; displacement of the follow-up mechanism shuts off the valve when the cylinder reaches the désired position. Being of a simple and straightforward type, motoring and hunting and other difficulties usually present in power position controls, are absent.

Hydraulic Follow-Up. Another method, shown schematically in Fig. 10, utilizing the "Adel isodraulic" system, has a hydraulic follow-up. It offers many advantages in weight saving, installation, simplicity, and smooth operation. It consists basically of three cylinders in parallel; cylinder 1 forming the master unit, cylinder 2 the valve-operating unit, and cylinder 3 the follow-up unit.

Working on the principle that with three cylinders in parallel, one being held, the second being moved, the third will move an amount equivalent to the first. Thus the follow-up cylinder is held by the power cylinder. As the master cylinder is moved, the second cylinder operates the 4-way valve which in turn applies pressure to the proper side of the power cylinder. Movement of the power cylinder operates the follow-up cylinder which automatically shuts off the valve when the desired position is reached.

Electrical Follow-Up. Utilizing the electric control on hy-

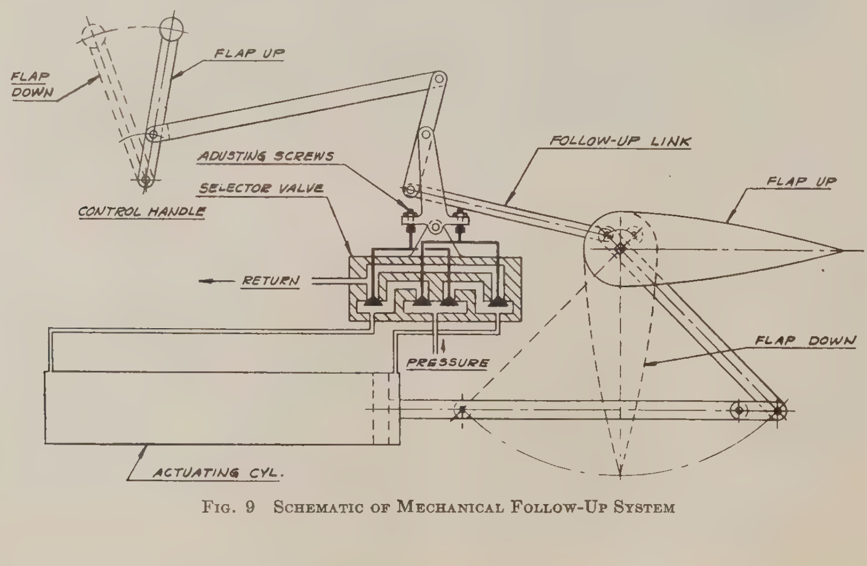

Fig. 9 Schematic of Mechanical Follow-Up System

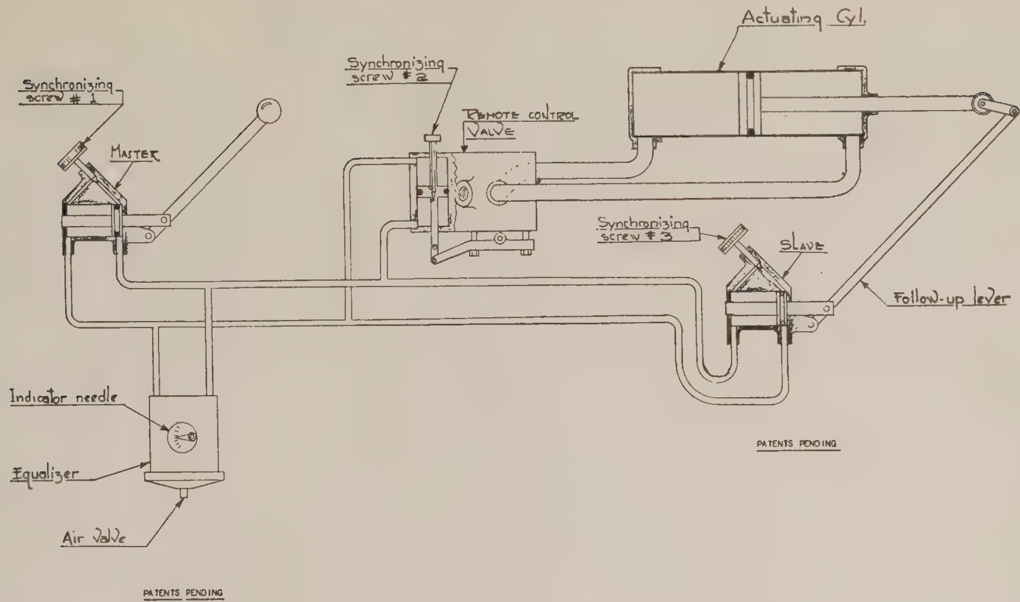

Fig. 10 Schematic of Hydraulic or Isodraulic Follow-Up System

draulic power, through the medium of a solenoid 4-way valve, another type of power-position-control combination is presented. Fig. 12 shows such a hydronic follow-up system. The master potentiometer upsets a bridge relationship with the follow-up potentiometer; thus the relay control box actuates the solenoid valve which in turn allows the cylinder to go to the desired position at which the follow-up potentiometer shuts the valve off.

"Hydronic" system, for long distances, is the lightest of the three, as shown in the graph, Fig. 13. Up to around 50 ft distance, the isodraulic position control enjoys weight advantages; and below 20 ft distance the mechanical system is the lightest.

Other factors, however, invariably enter into the follow-up choice. Actual position indication and system "feel" are naturally obtained in the mechanical and isodraulic; whereas, no feel is obtainable in the hydronic. Long distances are easiest to install with the hydronic, with the isodraulic coming second, and the mechanical third. The isodraulic and mechanical follow-up systems are self-contained and not dependent upon any outside source of power for actuation and followup; whereas, electrical power is required for hydronic operation. Multiple installations are easier to obtain electric-wise, requiring only slight revisions in circuits. For utmost simplicity and comprehension, when servicing in the field, the mechanical would rate first; with isodraulic second; and hydronic third.

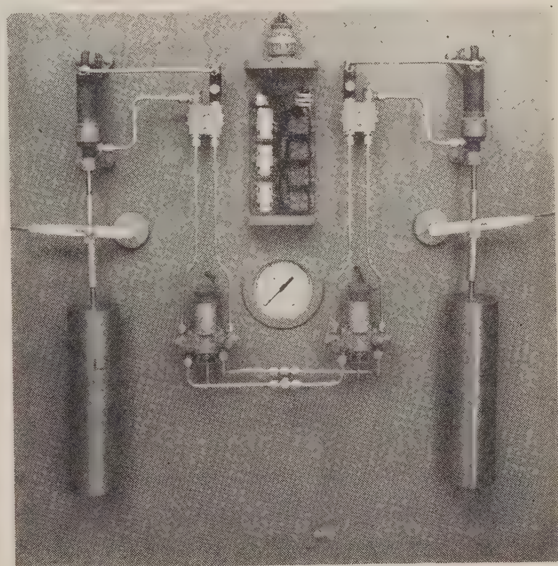

Fig. 11 Electrical or Hydronic Follow-Up System

Conclusion

Combination controls have presented many features which have and will be used to weight- and cost-saving advantages in the future as well as in the past. Actual manufacturing experience and operation of solenoid valves over the past several years have given much desirable and worth-while knowledge which allows us to design into these units more dependability and ruggedness than originally conceived.

Utilization of small electric motors, currently being supplied on other aircraft devices, has allowed us to design and build dependable motor-operated valves. Both solenoid- and motor-operated valves appear to be permanently in the picture and give the aircraft designer a wide choice of characteristics from which to choose.

The power package is beginning to come into its own; and as further improvements are made, weight-savings and operational advantages will become more and more apparent.

New methods and advancements of old methods on follow-up systems for hydraulic controls, utilizing basically mechanical, hydraulic, and electrical combinations, give to the industry versatility with smooth hydraulic power.

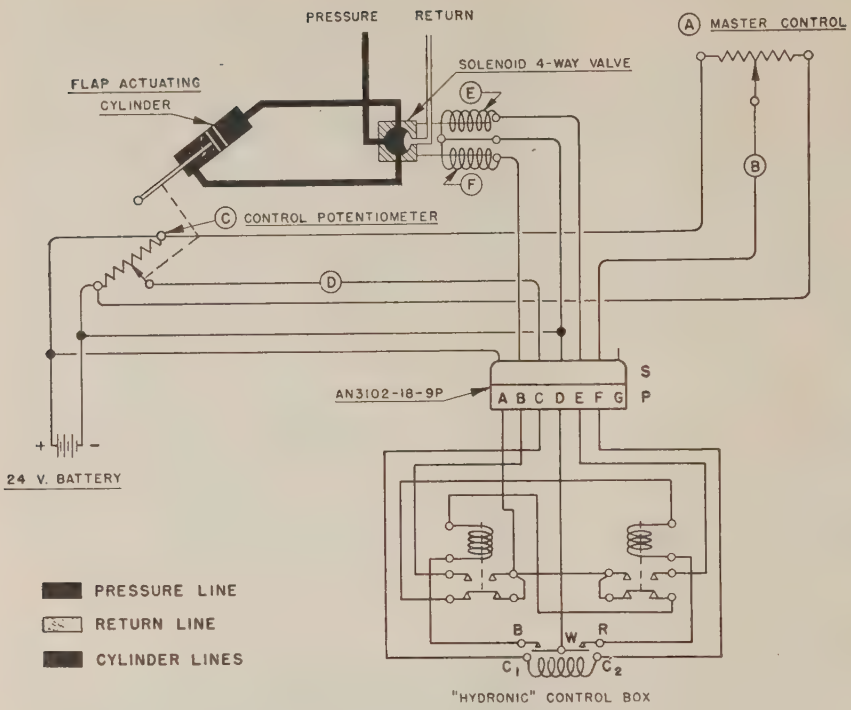

Fig. 12 Schematic Diagram of Follow-Up System Shown in Fig. 11

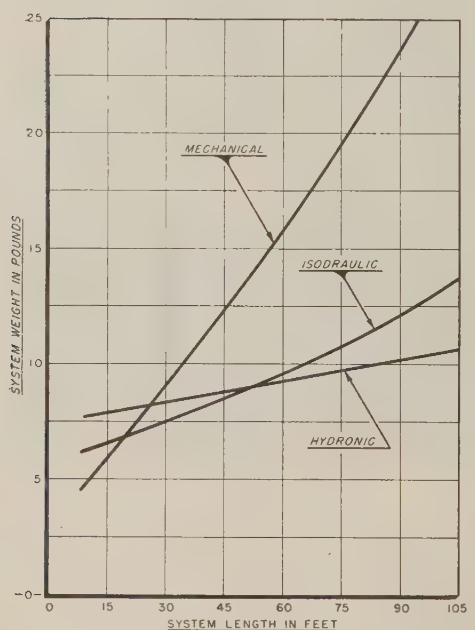

Fig. 13 Relative Weights of Power-Position-Control Systems

Discussion

R. A. Gund.[3] In discussing combination controls for aircraft, the author assumes that hydraulic power is the desirable power. It should be pointed out that for minimum weight the desirable power source may be either hydraulic or electric, depending on the characteristics of the load. Another factor which must be evaluated is the power supply on the aircraft—is it principally hydraulic or electric?

On large airplanes, where the power applications are generally located at some distance from one another, hydraulic lines are more difficult to run than electric wires. In military craft hydraulic lines are much more vulnerable.

The most versatile system would be one employing electric distribution with either electric or hydraulic power applied at the load, depending upon individual requirements. If, for instance, the load requires a starting torque of less than 6 times rated torque, an electric motor should be used to drive the load directly. This will result in minimum weight and maximum efficiency. On the other hand, if a very high torque load must be driven, hydraulic power can be advantageously applied by the use of the combination power package.

As an example, a split series-wound motor driving a screw jack could be directly substituted in place of the solenoid 4-way valve and hydraulic cylinder shown in Fig. 12.

Hydraulic power is most suitable for storing energy, as in power-boost systems and for hydraulic brakes.

Thus we may conclude that for minimum weight and maximum dependability all factors should be considered, and hydraulic power used only if it gives the most desirable results.

Author's Closure

In this paper the author has tried to avoid the controversial argument of hydraulic versus electrical modes of control. However, the author's assumption that hydraulic is the more desirable power source is further emphasized by Mr. Gund, and the arguments on the relative weight values of hydraulic and electric systems should be considered along with the many other factors involved before deciding which is the more desirable as a system.

The Effect of Measurement Dead Time in the Control of Certain Processes

By D. P. ECKMAN,[1] PHILADELPHIA, PA.

The purpose of this paper is to report on a series of automatic-control tests which demonstrate the importance of instantaneous controller-mechanism response in self-balancing potentiometer controllers. The automatic-control tests were made with both two-position and proportional-reset control. Other tests, dealing with the importance of measurement dead zone of the controller, are included, noting the relation between dead zone of measurement and dead time of controller response.

Introduction

One of the most important factors in automatic control of industrial processes is the manner in which the controller mechanism responds to changes in the measured variable. This measuring lag, as it is often called, forms an extensive part of the input-output controller-response relationship.

Generally, the factors of measurement dead time and dead zone are neglected in process-control analysis, particularly in mathematical analysis where their inclusion results in complications of a high order. Therefore it seems desirable to investigate the effect of these factors in automatic control in order to aid in the application of theoretical or empirical data to control problems.

Potentiometer controller mechanisms which incorporate continuous rather than periodic principles of rebalancing provide an opportunity for comparison test of these types of measuring means. Under simulated control conditions it is possible to analyze the dynamic action of the control system and the effectiveness of continuous measurement.

The measuring lag of a temperature controller is composed of two main parts: the lag of the primary element, and the lag of the controller detecting mechanism. It is this second part of the measuring lag, that due to the detecting mechanism, which we wish to study. For purposes of discussion we may classify the many methods of operation of self-balancing potentiometer controllers under two general types, i.e., periodic action and continuous action. A periodic-action potentiometer (recording type) is generally identified by a periodic mechanical system for detecting the position of a galvanometer pointer. When an unbalance of voltages is produced by a change in measured temperature, the detecting mechanism determines the amount of unbalance and drives a voltage divider or slide wire to balance against the new value of measured voltage. The periodic-action potentiometer is in wide general use for both measurement and control of process variables.

The continuous-action potentiometer (recording type) is generally identified (1)[2] by the use of continuous uninterrupted drive means, usually electronic, for obtaining the balance of measured against standard voltages. The use of continuous action in potentiometer balancing eliminates any lag due to a rebalancing mechanism, and avoids periodicity whereby a small dead time may elapse before changes in controlled temperature can be detected.

Tests With Two-Position Control

In order to determine the effect of dead time in the measuring system, it is desirable to conduct tests of two-position control. By this means all extraneous factors may be eliminated from the tests of automatic control. Processes were selected on the process-analog control board (2) by using various combinations of capacitance, resistance, and dead time.

The reaction curves for the processes to be tested are shown in Figs. 1 and 2. A reaction curve is determined by setting the

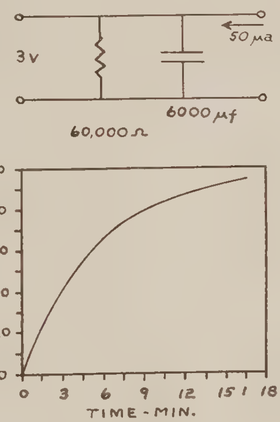

Fig. 1 Diagram and Reaction of Process No. 1

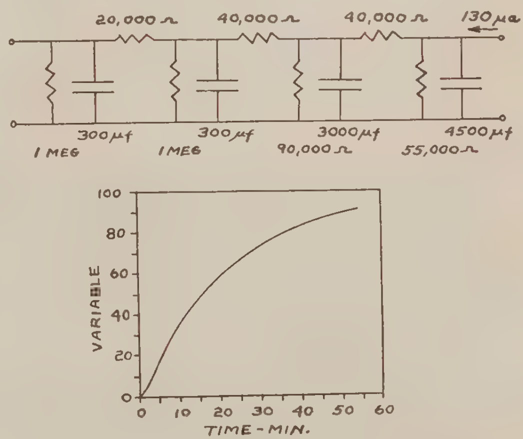

Fig. 2 Diagram and Reaction of Process No. 3

[1] Development Engineer, The Brown Instrument Company. Jun. A.S.M.E.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Industrial Instruments and Regulators Division and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.

valve position and allowing the measured variable to balance. A small sudden movement of the valve to a new fixed position will result in gradual increase of the measured variable to a new balanced value. The resulting time rate of change of the measured variable is the reaction curve. All processes indicate that self-regulation is present. Although the reaction curves are shown for only one direction of change, it may be assumed that the negative change produces a similar curve.

Process No. 1, shown in Fig. 1, is essentially a single-capacity process with a time constant of about 6 min, which is the time required to achieve 63 per cent of final value. Process No. 2 is identical in characteristics except that a dead time of 0.1 min was introduced between controller action and resultant valve movement.

Process No. 3, shown in Fig. 2, is a two-capacity process and thus involves slight transfer lag as can be noted by the slower initial rate of change on the reaction curve. Process No. 4 is identical in characteristics except that a dead time of 0.25 min was introduced between controller action and resultant valve movement.

Each process analog was connected, in turn, to the potentiometer controller. Each potentiometer controller, a periodic-action type and a continuous-action type, was fitted with both pneumatic and electric two-position "on-off" control. Pneumatic control was accomplished through a pneumatic diaphragm mechanism. The proportional band (throttling range) of the pneumatic on-off controllers was 0.6 per cent of controller scale. The on-off pneumatic controller is not actually a two-position controller but is a proportional controller with a very narrow band. This controller, however, is commonly termed on-off. Electrical control was arranged so that the control contacts directly actuated the energy supply to the process. The differential gap of both electrical on-off controllers was 0.05 per cent of controller scale.

With all process and controller combinations, a cycle of controlled variable was recorded. The resulting control cycle is described in Table 1 which shows amplitude, and Table 2 which shows period of cycle of the controlled variable.

TABLE 1 AMPLITUDE OF CONTROL CYCLE; PER CENT SCALE

Potentiometer controller with	Type of control	Process no. 1	2	3	4
Continuous action	Pneumatic	0.12	4.2	2.2	5.4
Periodic action	Pneumatic	1.80	4.6	4.2	7.1
Continuous action	Electric	0.25	3.8	2.3	6.1
Periodic action	Electric	1.00	4.2	4.0	6.8

TABLE 2 PERIOD OF CONTROL CYCLE; MINUTES

Potentiometer controller with	Type of control	Process no. 1	2	3	4
Continuous action	Pneumatic	0.10[a]	0.28[a]	2.4	4.5
Periodic action	Pneumatic	0.50	0.80	3.7	5.0
Continuous action	Electric	0.03	0.25	2.4	4.7
Periodic action	Electric	0.27	0.67	3.9	5.0

[a] Actually throttling to the extent that valve never completely opens or closes.

The results shown in Tables 1 and 2 illustrate the improvement caused by eliminating the dead-time delay in the potentiometer measuring means. This effect is particularly noticeable in processes Nos. 1 and 3, where all dead time in the controlled system is concentrated in the measuring means. In processes similar to No. 4 where considerable dead time exists in the process itself, the elimination of measurement dead time results in proportionately less improvement.

Dead time existing in any portion of the controlled system results in nearly proportional increase in amplitude. It is obvious that if automatic control is to maintain an adequate process balance then dead time in the controlled system must be reduced to a minimum.

Applying the results of these tests to applications of automatic control, it is probable that in electrically heated furnaces and baths where the process lags are very small, the elimination of measurement dead time would result in much closer temperature control.

On the other hand, when controlling the temperature of such processes as heat exchangers, where the process lags may be of minutes duration, the elimination of measurement dead time may bring no noticeable improvement.

It is interesting to note that the measuring lag may be computed from the results of controlling process No. 1 with the electrical two-position controller. Here virtually all of the lag aside from the time constant of the process is associated with the potentiometer measuring means. Since in two-position control the period of cycling is about 4 times the total lag (3), then the measuring lag should be the period divided by 4.

Thus the measuring lag calculates to be about 0.0075 min for the continuous-action potentiometer measuring means and about 0.0645 min for the periodic type.

Tests With Proportional-Reset Control

In order to demonstrate the effect of dead zone in the measuring means, a controller may be applied to a process, and the deviation during a recovery from a load change may be expected to show differences depending upon the magnitude of dead zone (4). The dead zone is generally defined as the greatest range of scale values within which changes in value of the controlled variable are not detected.

With self-balancing potentiometers, the width of dead zone is generally related to the construction of its detecting and balancing mechanisms. As one contributing factor, the width of dead zone is inversely proportional to the number of active convolutions of the potentiometer rebalancing slide-wire since the controller pen and controller mechanism are generally positioned to the convolution of the slide-wire nearest the balance point.

The self-balancing continuous-action potentiometer used in the previous tests has 1600 active convolutions on the slide-wire (1). It was desired to test this same potentiometer with 800 and 400 convolutions on the slide-wire, thus multiplying the dead zone by 2 and 4, respectively.

These arrangements were made by altering the mechanical relation between full-scale pen motion and slide-wire contactor travel. An oversize drum on the slide-wire driving shaft reduced the amount of slide-wire contactor motion while maintaining the same pen motion. This change does not alter the responsiveness of the potentiometer balancing motor to a given unbalanced emf, but reduces the amount of slide-wire contactor travel for the same pen travel when a rebalancing action occurs. The electronic voltmeter on the process-analog control board was then readjusted to maintain the same range of 0 to 5 volts for full-scale pen travel.

The net result of these changes is to alter the number of slide-wire convolutions corresponding to a given pen travel while maintaining the same dynamic balancing action and the same scale calibration.

Three processes were selected and are described in Figs. 3, 4, and 5. Process No. 5, described in Fig. 3, is a relatively simple process having a moderate reaction rate and slight transfer lag Process No. 6, described in Fig. 4, possesses a moderate reaction rate and appreciable transfer lag. Process No. 7, described in Fig. 5, has a fast reaction rate and slight transfer lag. In all tests only the dead time inherent in the system was present and no dead time was intentionally added.

Each process analog was connected to the potentiometer controller and optimum adjustments of proportional band and reset rate selected (5). A pneumatic proportional-reset type con-

(25 per cent band, 3 per min reset rate. 1 time division equals 4 min.)

troller was employed for these tests. After the controlled variable had stabilized, a change in supply of energy to the process was made and the controller recovery curve obtained.

The supply change was introduced by adding a bias voltage to the existing voltage supplied to the current-input unit on the process-analog control board. This is, in effect, a change of flow through the control valve caused by a variation in pressure drop and requires that the controller correct for this change. The control valve has 200 effective positions.

The charts showing the recovery curves are reproduced in Figs. 6, 7, and 8. The results of these tests are given in Table 3.

TABLE 3 RESULTS OF TESTS

Process no.	Prop. band, per cent	Reset rate per min	Maximum deviation for ± supply changes — No. of effective convolutions: 1600	800	400
5	45	0.8	11.2	11.7	..
6	60	0.4	16.7	17.7	18.1
7	25	3.0	10.0	10.4	10.6

As shown by the recovery curves in Figs. 6, 7, and 8, both an increase and a decrease in supply were made. The increase in supply results in a rise of the controlled variable before it is corrected by the controller, and a decrease in supply results in a fall of the controlled variable before it is corrected. The maximum deviation was found by adding both the positive deviation and the negative deviation. In this manner various small nonlinearities in valve characteristics, process time-constant, and process lag may be averaged.

The difference between the various maximum deviations from a supply change may be attributed to the different widths of measurement dead zone in each test. With a larger dead zone, a short period must elapse between the time when an actual change in measured variable begins and the time when the controller senses the change. Thus a measurement dead zone creates dead time. This delays the controller corrective action and allows greater deviation.

The stability of control appears to be more cyclic when the dead zone is greater. With process No. 6 particularly, the recovery curve shows that the proportional band should be slightly increased in order to maintain the same ratio of succeeding amplitudes of cycling. There is an appreciably consistent lengthening of period when the dead zone is greater. The apparent decrease in stability of control and the lengthening of period of control points to the conclusion that an additional lag exists when the measuring means of the controller possesses a finite dead zone.

Conclusion

The brief test results given here illustrate the importance of measuring lag and measurement dead zone in automatic control. It is desirable to maintain measurement dead time as small as possible since it increases the quality of control, especially on such processes where all other lags are small. It is desirable to maintain measurement dead zone as small as possible since it increases the quality of control by accomplishing a reduction of dead time.

It is evident that more investigation is required to establish further the relationship between each component part of measuring lag and the measurement dead zone. In most control problems the effect of these factors cannot be ignored because of their influence on the quality of automatic control.

Discussion

W. F. Hickes.[3] The author has shown us the detrimental effect of "dead time" in process control and has presented some evidence on the effects of "dead space" in terms of slide-wire turns. The results are interesting because they confirm the conclusions reached in our own laboratory investigations and field work.

It is difficult in practice to speak of dead time without bringing in dead space and vice versa because the two are so closely related. Let us assume we have a furnace at 1500 F. Let us further assume that with full heat on we have a heating rate of 5 deg F per min. Now if we have an instrument with a 0 to 1600-deg scale range and 1600 slide-wire turns, each turn will represent 1 deg, that is, the instrument will have 1 deg dead space. With a 5 deg per min change of temperature, the instrument should move every $^1/_5$ min and can hardly be much better than a periodic instrument with a dead time of $^1/_5$ min and could be expected to be inferior to a periodic instrument with the usual period of $^1/_6$ to $^1/_{10}$ min. It might be added that the figures quoted represent an actual furnace installation.

In comparing measuring instruments the author has described two types, the so-called continuous and the periodic. Actually there are at least four types. There is the periodic type described by the author, which has dead space due to slide-wire turns and dead time due to its periodic balancing action. There is another type which has dead time but not dead space, since the slide-wire serves only to set the control point, and the control mechanism operates directly from the galvanometer deviation. This type is nonrecording but has been very successful as a controller. There is the "continuous" type, cited by the author, which eliminates dead time by its continuous action but which still has the dead space due to slide-wire turns. There is finally a fourth type which has inherently neither dead space nor dead time, the dead time being eliminated by the same type of continuous balancing as in the previous case, dead space being eliminated by the substitution of stepless balancing for the conventional slide-wire.

The author has stated that the elimination of dead time is of greatest value where process lags are small and may bring no noticeable improvement where lags are large. This is undoubtedly correct although it should be realized that the typical thermal processes of inconsequential lags such as heat-treating furnaces have in general relatively slow maximum rates of temperature change so that dead time may be much less objectionable than dead space.

The really interesting cases would appear to lie in the extension of electronic controls of these general types to problems involving pressure and flow control. There are at present several makers offering units to convert pressure and differential pres-

[3] Foxboro Company, Foxboro, Mass.

sure into electrical values such as resistance which can then be measured on the type of instruments described. Since pressure and flow controls are normally characterized by very small lags and in many cases also by very rapid changes, the value of a truly continuous instrument free from inherent dead space as well a dead time should be apparent.

Author's Closure

The discussion of Mr. Hickes is greatly appreciated since it brings out many of the factors affecting the quality of automatic control when controller dead zone is present. As is stated, in control problems of inconsequential lag measurement, dead time becomes an appreciable factor.

Mr. Hickes's conclusion with regard to dead time due to dead zone is open to controversy because having a slidewire in which one convolution represents an interval of 1 F is not identical to having a dead zone of 1 F. Without going into the many details involved, a high amplifier "sensitivity" produces a condition wherein a rise in thermocouple emf will cause the slidewire contact to move entirely across one convolution to the edge of the adjacent convolution. Thus with gradually changing temperatures it is possible to obtain a relatively greater response with a slidewire balancing device having discreet positions than with a continuously balancing device.

With respect to measurement and controller dead zone, there are four general cases: (*a*) Control systems and process with a relatively fast reaction rate and little lag, (*b*) with relatively slow reaction rate and little lag, (*c*) with relatively fast reaction rate and large or appreciable lag, and (*d*) with relatively slow reaction rate and large or appreciable lag. The effect of dead zone is different in each case.

For example, in process control with fast reaction rate and little lag such as in flow or speed control, the author has observed cases of pseudo stability at narrow proportional bands which, with large, sudden upsets become cyclically unstable, sometimes violently so. This passage from the stable to the unstable region is apparently initiated by a fast change of the controlled variable through the dead zone and there may be little subsequent evidence of a square top wave.

With processes having a slow reaction rate and appreciable lag, the dead zone evidences itself as a consistent, additional lag and the quality of control is proportionately reduced.

Mechanical Oscillators and Their Electrical Synchronization

By S. W. HERWALD,[1] R. W. GEMMELL,[2] and B. J. LAZAN[3]

Mechanical oscillators provide an excellent means for obtaining structural serviceability tests. The adjustable-while-running type is particularly flexible. With it the answers to certain fundamentally difficult problems can be obtained quickly. The electrical system presented provides accurate remote control of frequency and phase angle between forces of two or more mechanical oscillators. In addition, means are incorporated for changing and indicating remotely the amount of unbalance of each oscillator unit. Rototrol units used with electronic and magnetic controls are the basic elements of this precise servomechanism.

HIGHER speeds in modern transportation and machinery, and present-day design trends toward greater efficiency and lighter weight have emphasized the importance of dynamic forces as a factor in design. The urgency of dynamic testing of materials and structures is indicated by a few recent studies (1),[4] which show that very few service failures in machine and structural members can be attributed to static forces alone; over 80 per cent involve dynamic forces.

Practical mechanical testing may be of three types, as follows:

(*a*) Testing carefully prepared specimens under simplified conditions of stress and environment to determine basic material properties.

(*b*) Testing actual shapes, assemblies, or structures under conditions which closely simulate actual service to secure direct design data.

(*c*) Testing in actual service.

Theoretically, if basic material properties and service conditions are known, one should be able to predict the behavior of a structure. Reasonable success has been achieved in such analysis of structures under static loads. However, predicting the behavior of a structure under dynamic loads in this manner is often unreliable because of such difficult variables as stress concentration, natural frequencies, damping, load distribution, etc. Thus past experiences indicate that at present the best procedure is to use specimen testing as a guide to the selection of materials and as an aid during the initial design stages; but to rely on structure testing for refining a design and checking actual serviceability.

Of course, no test of serviceability is as foolproof as actual service. However, to rely exclusively on actual service is usually impractical, time-consuming, and very expensive. Thus the simulated service test is a vital link in modern engineering analysis.

One of the most useful tools in simulated service tests is the mechanical oscillator, a device for producing sinusoidal alternating force or torque of controlled magnitude, direction, and frequency. Generally, it is a portable machine which may be carried to the structure and attached to it for field testing. Oscillators of this type are particularly useful in producing sinusoidal forces of large magnitude at relatively low frequencies. Furthermore, two or more of these oscillators can be connected electrically so that a definite phase relationship of the force outputs can be maintained. This provides the possibility of a more complete test, because a number of definitely related forces can be introduced to the structure simultaneously.

The Mechanical Oscillator

Probably the first mechanical oscillator capable of producing linear sinusoidal force was developed by W. Spath (2) in 1928, for testing railroad bridges. This oscillator utilizes the centrifugal force of eccentrically supported rotating masses as a source of alternating force (see Fig. 1). An eccentric E is attached to each of two shafts S which are motor-driven and geared so as to rotate in opposite directions. When both eccentrics E point vertically downward, position a in Fig. 1(a), the radial centrifugal forces add and the resultant force is vertically downward. After 90 deg of rotation to position b, the two centrifugal forces point in opposite directions and cancel each other. When the eccentrics reach position c they again add to produce a vertically upward force, and at position d they again cancel. In general, the net force is the vector sum of the two radial centrifugal forces, which is a sinusoidal alternating force such as shown in Fig. 1(b).

The same oscillator may be arranged to produce pure torsional vibration about an axis perpendicular to the plane of the paper at b in Fig. 1(c), by driving shafts S in the same direction and rearranging the eccentrics as shown.

The frequency of the alternating force equals the frequency of rotation of the oscillator, and the magnitude of the force equals the total inch-pound unbalance in eccentrics E multiplied by the angular velocity squared. The value of the unbalance can be adjusted by changing either the radial location or the size of eccentric E.

Variations of the Spath unit have been developed using four (3) or six (4) eccentrics, or using a different arrangement for the eccentrics so as to permit greater flexibility in governing the direction of types of possible forces. Oscillators have been built (4) capable of producing alternating forces as high as ± 44,000 lb; others have unbalanced masses with eccentricity as high as 6800 in-lb.

In many types of tests it is imperative that the weight of the oscillator be kept to a minimum. Mechanical oscillators developed to meet this requirement include the scotch yoke and the hypocyclic oscillator (3). However, none has been as successful as the centrifugal-force type from point of view of simplicity of operation, ease of maintenance, and purity of the sinusoidal force. The scotch-yoke oscillator, for example, generally induces rather severe harmonics which make analysis of results difficult.

During the dynamic testing of a structure it is generally necessary to cover a wide range of alternating forces. In the early os-

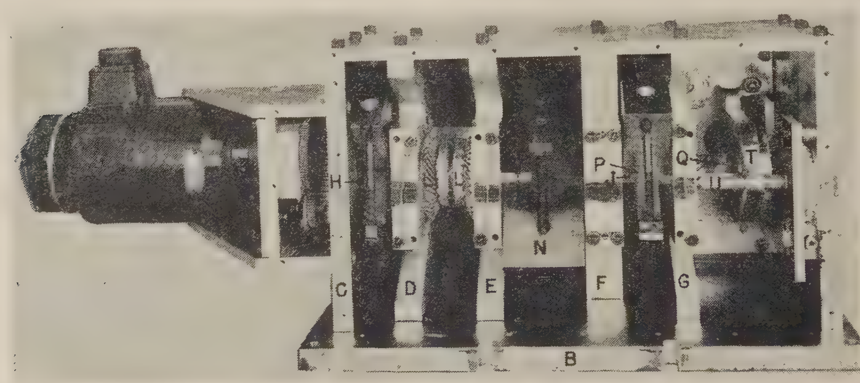

Fig. 2 Adjustable-While-Running Oscillator of the 45-Deg Rack Type With Drive Motor and Synchronization Control Equipment Attached

cillator every change in unbalance required stopping the unit and manually moving or changing the eccentric. This procedure not only consumed time, but also made certain types of tests very difficult. Recent improvements in centrifugal-force oscillators permit stepless adjustment of unbalance without stopping the unit. This may be accomplished either by adjusting a remotely controlled electric drive or by turning a knob attached to the oscillator.

Three different types of unbalance-changing mechanisms have been used: (*a*) differential gear changer (5); (*b*) helical key changer(6), which is now the most popular adjustable-while-running oscillator in use; and (*c*) 45-deg rack changer. Inasmuch as the special electric synchronization equipment to be described later was developed for the oscillator with the rack changer, this unit will now be described in detail.

The principle of operation may be understood by referring to Fig. 2. The oscillator consists of a base plate *B* to which are mounted pedestals *C*, *D*, *E*, *F*, and *G*. The ball bearings contained within the pedestals support rotating shaft *H* between *C* and *D*, rotating shaft *I* between *E* and *F*, and rotating shaft *J* between *F* and *G*. Shafts *H* and *J* are mechanically connected by a shaft running through the center of *I* so that they rotate together at the same speed and in the same direction. Spiral bevel gears *L* connect shafts *H* and *I* so that they rotate in opposite directions but at the same angular velocity. An eccentrically supported mass is attached to each of the three rotating shafts; eccentric *M* to shaft *H*, eccentric *N* to shaft *I*, and eccentric *O* to shaft *J*. At any given setting of the oscillator, eccentric *N* has an inch-pound unbalance equal to the sum of the unbalance in eccentric *M* and *O*. Furthermore, the inch-pound eccentricities in *M* and *O* are inversely proportional to the distances of *M* and *O* from eccentric *N*. This results in cancellation of moments.

Since eccentric *N* rotates in one direction as eccentrics *M* and *O* rotate at the same velocity in the opposite direction, pure sinusoidal force results (see previous explanation of Spath unit). It is possible to produce sinusoidal vibration in any direction perpendicular to the axis of rotation by unmeshing gears *L* (which enables shaft *I* to turn freely without a corresponding rotation of

shafts H and J), turning shaft I as desired, and remeshing the gears L.

The unbalance of all three eccentrics may be remotely and steplessly varied from zero to the maximum value while the oscillator is either stationary or running. This is accomplished as follows:

Each eccentric consists mainly of a large unbalanced mass and two racks P containing square teeth which make a 45-deg angle with the axis of the rack. These straight racks P slide in rectangular slots cut in the three shafts H, I, and J. Contained within these three tubular shafts are round members Q which have 45-deg square teeth cut on two sides to mesh with the 45-deg teeth on straight racks P. Thus as racks Q are moved axially, the meshing teeth will cause straight racks P to move radially, thereby changing the radial location of the center of gravity of the eccentrics. At zero unbalance, racks Q are so located that the center of gravity of the eccentric assembly consisting of P, etc., is at the center of rotation. To increase the eccentricity, the center of gravity of the eccentric is moved radially outward from the center of rotation.

Ball bearings contained within the shafts H, I, and J hold the racks in rigid axial location, but allow them to have angular freedom so that they can rotate with the parts they locate. This axial location is determined by the position of yoke T which is moved by motor-driven worms and screws U to adjust the radial location of the eccentrics.

This oscillator has a maximum unbalance of 150 in-lb and can produce alternating forces up to $\pm$ 1000 lb at speeds as low as approximately 500 rpm. Further refinements incorporated in this unit will be discussed in another section.

Fig. 3 Aircraft Rototrol of 3000 W

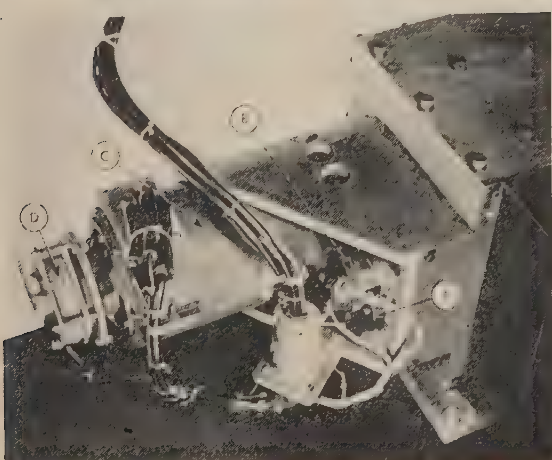

Fig. 4 Drive-Motor End of 45-Deg Rack-Type Oscillator

Electrical Control

The basic electrical equipment used to control accurately the frequency and force-phase relationship of two oscillators of the type shown in Fig. 2 is the Rototrol (7). This machine is illustrated in Fig. 3. When it is used with the proper electronic control, it provides the power required for precise regulation of the oscillator drive motors. The drive motors, shown as C in Fig. 4, rotate the unbalanced masses in the oscillators, producing sinusoidal forces in the manner described in Fig. 1. The motor shown is rated 3 hp at 3600 rpm.

Complete control of both oscillator units is obtained at the control box shown in Fig. 5. From here the speed of the oscillators,

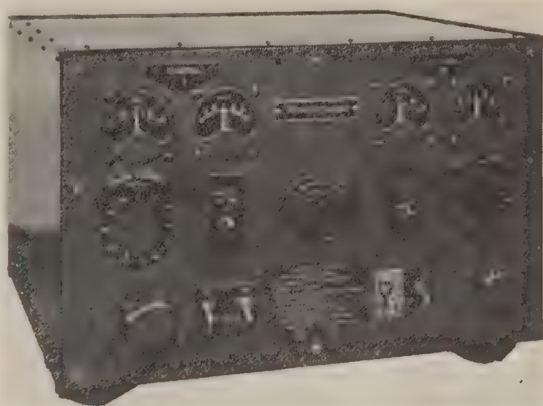

Fig. 5 Front View of Oscillator Control Box

Fig. 6 Front View of Oscillator Indicating Panel

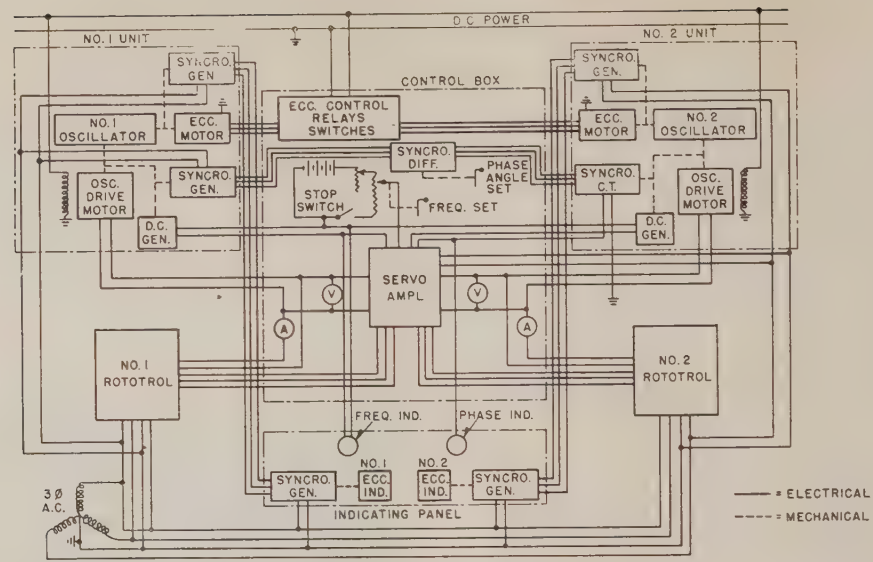

Fig. 7 Schematic of Frequency, Synchronization, and Eccentricity Control of Two Oscillator Units

the phase angle between their force outputs, and the amount of unbalance in each unit can be varied while the oscillators are running. Here also are the normal and emergency braking switches used to obtain decrement curves and emergency shutdown, respectively. Frequency can be fixed at anywhere from 100 to 1800 cycles per min; phase angle between forces can be fixed anywhere between zero and 360 deg; unbalance can be changed from zero to 150 in-lb on each oscillator independently.

Fig. 6 shows the indicating panel associated with this equipment. It contains the test record and is conveniently arranged for photographing. Thus the time of test, the frequency, the eccentricity in each of the units, and the phase error between the units can all be obtained on one photograph. The phase error mentioned should not be confused with the phase-angle setting on the control panel. Phase error is merely the inaccuracy of the phase angle as set on the control unit. The phase-error meter reads directly in degrees. In operation it showed substantially less than ± 15 deg, even with large eccentricities and with the units 180 deg out of phase.

The schematic diagram of the electrical system used to control the oscillators is given in Fig. 7.

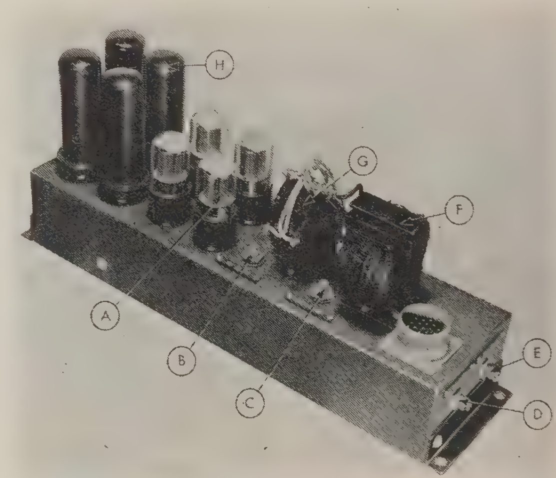

Fig. 8 Two-Channel Servoamplifier

Frequency and Phase Control

For the No. 1, or master unit, a desired frequency is maintained within close limits by matching the preset portion of the control-unit battery voltage with that of a d-c tachometer generator A, Fig. 4, driven by the No. 1 oscillator motor C, Fig. 4. The voltage difference which occurs when the generator voltage does not match the battery potentiometer voltage is fed into the amplifier, Fig. 8. The amplifier output controls the output voltage of the No. 1 Rototrol generator which in turn changes the speed of the No. 1 oscillator drive motor so as to reduce the voltage error between the tachometer generator and the preset portion of the battery voltage. Thus except for a very small voltage difference required to produce enough Rototrol output voltage to maintain the oscillator drive motor at the required speed, the system is self-compensating, tending always to reduce the voltage error. Since a d-c tachometer generator produces a voltage that varies linearly with speed, all one has to do to vary frequency is to adjust the battery potentiometer B, Fig. 9. This, of course, causes the drive motor to change speed so that the tachometer voltage again matches the portion of the battery voltage picked off by the potentiometer.

The No. 2 unit operates in a similar manner, except that there is one added feature. In order to maintain a given phase relationship between the Nos. 1 and 2 units, a synchrosystem is used to detect error from the desired phase relationship. This error is detected as an a-c voltage that varies as the sine of the angle of deviation from the desired phase relationship of the Nos. 1 and 2 units. An electrical schematic of this synchrosystem is shown in Fig. 11. The rotor of the synchrogenerator which has salient poles is excited single phase. This sets up the flux field A which cuts the stator windings. These stator windings are usually displaced mechanically 120 deg and connected to exactly similar windings of the synchrodifferential. The currents that flow in similar windings such as a and a' or b and b' of the generator stator and the differential rotor are identical. Therefore flux field B has the

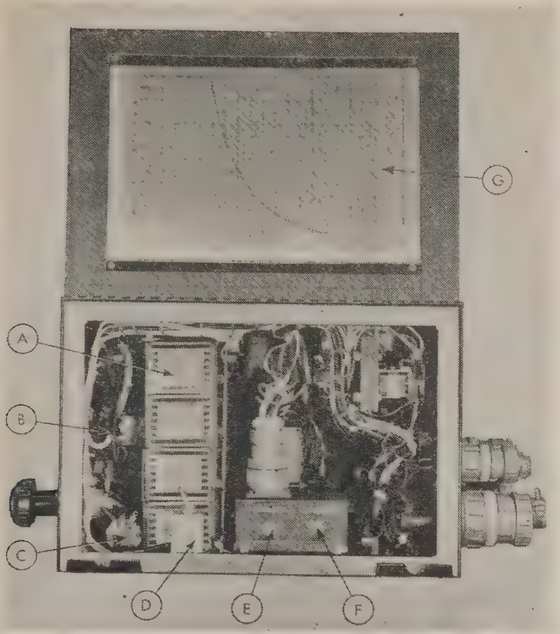

Fig. 9 Right-Side View of Oscillator Control Box

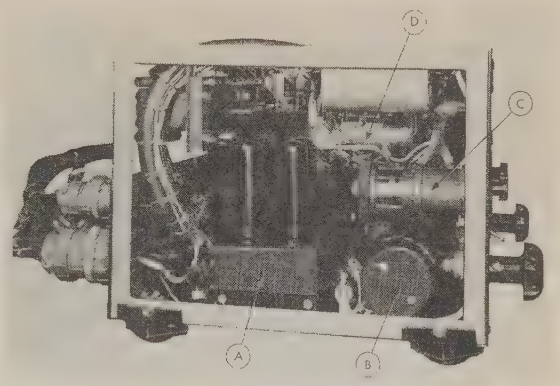

Fig. 10 Left-Side View of Oscillator Control Box

same position relative to the windings as flux field A and the windings have served as a means of indicating generator-rotor position in the differential. Similarly the combination of the synchrogenerator-rotor and the differential-rotor positions is indicated by the synchrocontrol-transformer flux field C. Thus the apparent position of the generator rotor as indicated to the control transformer by flux field C can be changed by rotating the synchro differential rotor.

The control transformer is similar to the synchrogenerator except that the rotor has a distributed winding to reduce reaction torque. With the synchrocontrol transformer rotor in the position shown in Fig. 11, no error voltage appears across terminals T_1 and T_2 as the rotor is at right angles to the flux field C. As the rotor is rotated the component of flux intercepted is proportional to the sine of the angle of rotation, consequently, the error voltage at T_1 and T_2 also varies as the sine of the angle of control-transformer-rotor rotation. The rotation of either the synchrogenerator or differential rotor produces a voltage at T_1 and T_2 that varies as the sine of the angle of rotation. This occurs because movement of either rotor shifts flux field C relative to the control-transformer rotor.

If the generator and control-transformer rotors are rotated at exactly the same speed the voltage at T_1 and T_2 does not vary as the relative position of flux field C and the control-transformer rotor does not change.

As used in this system the synchrogenerator B, Fig 4, is driven by the No. 1 motor and is electrically connected through the synchrodifferential C, Fig. 10, in the control unit to the synchrocontrol transformer which is physically located on the No. 2 unit exactly as in B, Fig. 4. The control transformer is driven by the No. 2 motor. The phase-relationship-error voltage obtained from the synchrosystem, as described, is superimposed on the frequency control in the amplifier channel for the No. 2 unit.

The voltage output of the No. 1 tachometer generator is used to give an indication of the frequency. A voltmeter, see Fig. 6, in the indicating panel, calibrated in cycles per min, is used for that purpose. The control-transformer error voltage, which is a measure of the phase-angle error between the Nos. 1 and 2 units, is indicated by an a-c voltmeter on the indicating panel. This phase-angle error is required so that enough control-transformer error voltage is produced at the No. 2 unit amplifier channel to hold a fixed phase relationship between the Nos. 1 and 2 units.

Eccentricity Control

The eccentricity of an oscillator unit is varied by operating a switch on the control-unit panel. It is a two-way momentary "on" switch, and by using relays and limit switches D and E, Fig. 12, the eccentricity motor B, Fig. 12, is operated in either direction so as either to increase or to decrease the eccentricity.

A synchrogenerator C, Fig. 12, is driven by the eccentricity motor. By electrically connecting this synchrogenerator to a similar one in the indicating-panel unit which drives a counter, an indication of the eccentricity in each of the units is obtained. This, of course, is the standard synchrotie connection. The

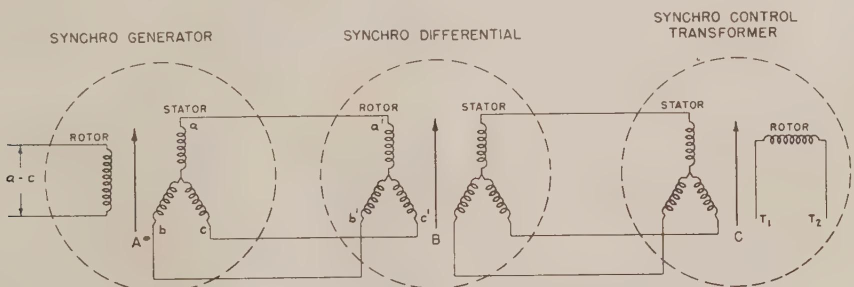

Fig. 11 Synchrosystem Schematic

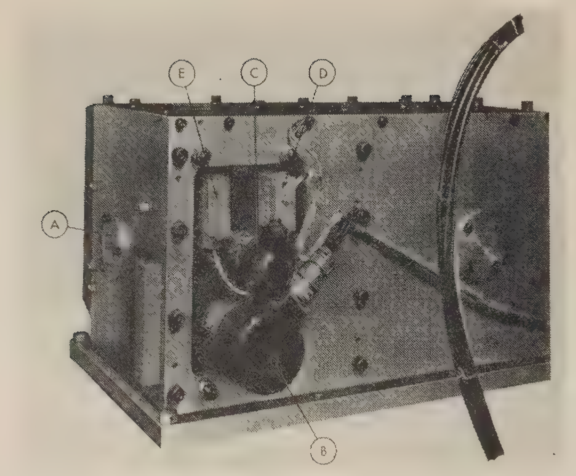

Fig. 12 Eccentricity Motor End of 45-Deg Rack-Type Oscillator

amount of unbalance in the unit can be determined mechanically by inserting a calibrated needle gage in bolt hole of *A*, Fig. 12.

Amplifier Operation

The amplifier shown in Fig. 8 is used as a means of detecting the low-power-level intelligences offered by the battery, d-c tachometer, and synchro machine circuits, and of converting them almost instantaneously into intelligence at a power level sufficiently high to control a Rototrol generator-control field. A Rototrol is in itself a fine power amplifier. Its power output, which is regulated by the control field, is great enough to run an oscillator drive motor, and yet it is a fast machine electrically, responding quickly to the intelligence the amplifier transmits to its control field.

The Nos. 1 and 2 channels of the amplifier are similar. Each has two stages of push-pull d-c voltage amplification for which a pair of 6SL7's are used, *A* Fig. 8, and one push-pull power-amplification stage in which two 6L6's, *H* Fig. 8, are used. A dynamotor *B*, Fig. 10, supplies direct current for the plates of the 6SL7's, whereas the plate supply for the 6L6's is alternating current. Each pair is supplied by a separate secondary winding of the same transformer. The difference between the two channels of the amplifier is that the synchrocontrol-transformer error voltage is introduced into the No. 2 channel only. This locks the No. 2 oscillator in a definite phase relationship to the No. 1 oscillator. As previously described, this phase relationship can be varied from zero to 360 deg by rotating the differential synchromachine rotor.

As in the case of all servomechanism (8) systems, proper damping means must be used to prevent "hunting." In this oscillator system damping is obtained by derivative feedback from the Rototrol armature circuit.

Conclusion

During the past 17 years the use of mechanical oscillators for simulated service testing has enjoyed steady growth. Originally developed for testing railroad bridges, oscillator testing has been found applicable to testing many other types of structures, such as aircraft, land vehicles of all types, buildings and foundations, and ships. In testing such structures mechanical oscillators have been used to determine such properties as fatigue strength, natural frequency of vibration, damping capacity, resonant stress, flutter, riding comfort, and other vibration-response characteristics. Oscillators have also been used for many types of soil investigation (such as the behavior of an airport landing strip under vibration), and as a laboratory tool to study fatigue, stress-relief possibilities, dynamic modulus of elasticity, dynamic creep, etc. A relatively small oscillator is a particularly powerful dynamic testing machine when used to produce resonant vibrations; under these conditions the force exerted on the part under test may be from 10 to more than 100 times the oscillator force (3).

Certain types of dynamic testing require two or more oscillators properly synchronized and controlled to induce a desired vibration. For example, one method of determining flutter characteristics in aircraft wings is to attach an oscillator to each wing to excite controlled and properly synchronized vibrations during flight. The equipment described in this paper will perform such a task. The combination Rototrol and electronic control will maintain precisely the frequency and phase relationship of two or more oscillators. Additional electrical control provides means of adjusting the frequency, phase, and eccentricity of the oscillators while the units are operating.

Precision Tachometer for Use in Wind-Tunnel Testing

By R. K. FAIRLEY[1] and H. L. CLARK[1]

The equipment described is a high-speed high-accuracy tachometer developed primarily to measure rotative speed during the power-testing of airplane models in wind tunnels by measuring the frequency of a tachometer generator. The frequency being measured is automatically compared with that of a tuning fork and indicated on an instrument having a scale length of 86 in.

One of the largest laboratory devices we have today is the modern wind tunnel, built to analyze the performance of planes and their component parts. While all tunnels are custom-built, they have one common characteristic, that is, the need for many accurate instruments. In addition to fairly good accuracy, good precision is also required since precision or constancy of indication will reveal trends resulting from model changes.

To build instruments of the accuracy required is sufficiently difficult, but to add to the difficulty, such instruments should be self-reading or recording. As the design of airplanes increases in complexity, the number of instruments which must be read simultaneously is multiplied. To expedite research work, not to mention economics which is sometimes forgotten under the stress of war work, it is highly desirable to obtain such readings at the touch of a button. Automatic recording avoids the errors of an observer, particularly those caused by fatigue. Not only are such errors obviated by self-recording features, but such readings may also be recorded in a calculating machine and much laborious manual calculating work avoided.

Some phases of model testing involve so-called "power on tests." This means that the model plane will be provided with a propeller and a power plant, usually an electric motor or motors. When a test is in progress it is necessary to know accurately the speeds of these electric power plants and the developed torques. Torque is usually measured indirectly, first, by calibrating each motor in a dynamometer and measuring the electrical input at each given speed. The motor is then mounted in a model plane in the wind tunnel, and at the same speed, the same watts, volts, and amperes are applied and the calibrated torque obtained.

During a test run the watts, volts, amperes, and speed are continuously measured and numbers set up in a printing machine. When stable conditions are reached these quantities, together with their associated multipliers, etc., are simultaneously recorded in the printing machine.

It is the purpose of this paper to describe the equipment which measures the speed and actuates the printing machine.

Principle of Operation

Accurate measurements are usually facilitated by comparison with a known value, commonly referred to as a standard. For example, accurate measurements of weight can better be made with a balance, using tested weights, than with a spring scale. The balance uses the comparison principle while the spring scale uses the deflection principle.

A similar principle applied to the measurement of frequency is often used employing an oscilloscope and Lisajou figures. The ratio between the unknown and known frequencies, such as $^3/_4$, $^5/_6$, etc., is deduced from the shape of the pattern. The equipment to be described automatically obtains this ratio using a self-contained known frequency, and indicates the value of the unknown frequency on a special long-scale instrument.

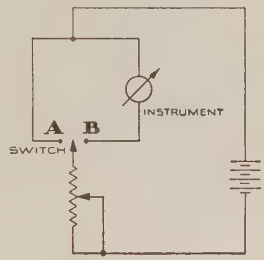

Fig. 1 Basic Circuit, Deflection Principle

A simplified circuit showing the principle of operation is illustrated in Fig. 1. The switch, normally in position A, snaps over to position B at the beginning of the cycle being measured. This is shown at point 1 in Fig. 2(a). After a definite length of time this switch automatically switches back to position A and stays there until the beginning of the next cycle of the frequency being measured (point 2). Current will flow through the instrument while the switch is in position B. The wave shape of this current is shown in Fig. 2(b), in which t_1 shows the definite length of time the switch stands in position B, and t_2 is the time for one cycle of the frequency being measured. The instrument will indicate the average value of the current, shown as i_{av}. When a higher frequency is being measured, as shown in Fig. 2(c), the switch snaps from position A to position B at the beginning of the cycle, stands in position B for the same definite length of time as before, then snaps to position A, and then waits in position A until the beginning of the next cycle. The current flows through the instrument as shown in Fig. 2(d). Since the pulses of current are spaced more closely together, the average current will be higher. This average current is given by

$$i_{av} = i_{max} \frac{t_1}{t_2} \qquad [1]$$

Since the frequency being measured is

$$f = \frac{1}{t_2} \qquad [2]$$

the average current is then

$$i_{av} = i_{max}\, t_1 f \qquad [3]$$

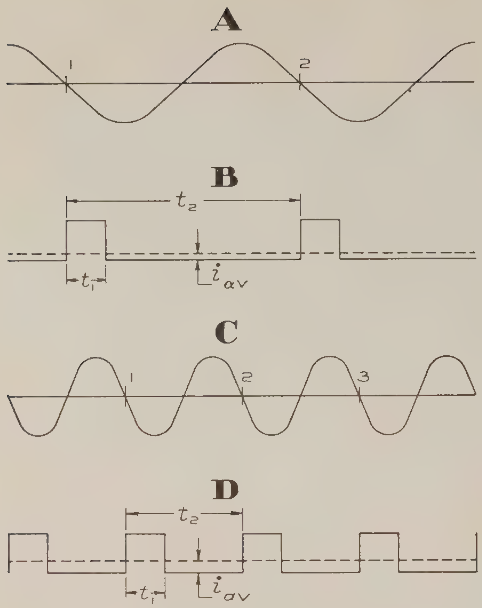

Fig. 2 Current Impulses, Showing Operation of Switch

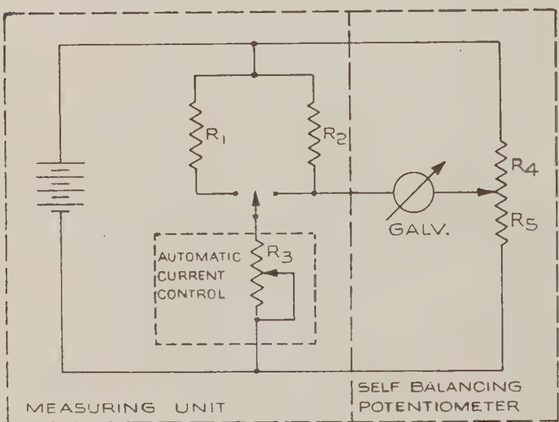

Fig. 3 Basic Circuit, Balance Principle

Equation [3] shows that the average current through the instrument is proportional to the frequency being measured.

However, the use of an ordinary indicating instrument to measure the average current makes use of the deflection principle instead of the more accurate comparison principle. Rearrangement of Equation [3] gives

$$\frac{i_{av}}{i_{max}} = t_1 f \qquad [4]$$

Here we see that the ratio between the average and maximum current is proportional to the frequency being measured since t_1 is a constant.

This ratio may conveniently be measured by using a self-balancing bridge, the basic circuit of which is shown in Fig. 3. The bridge consists of resistors R_2, R_3, and R_4 plus R_5 which is a self-balancing potentiometer. (The resistor R_3, denoted "Automatic Current Control," is required to hold the current through this arm of the bridge strictly proportional to the supply voltage. This is necessary because of the somewhat variable voltage drop across the switching element which is to be described later.) The voltage across R_2 is proportional to i_{av}, while the voltage across R_2 plus R_3 is proportional to i_{max}. When the slider on the potentiometer is adjusted so that no current flows through the galvanometer

$$\frac{i_{av}}{i_{max}} = \frac{R_4}{R_4 + R_5} = t_1 f \qquad [5]$$

Here we see that the value of the frequency being measured is determined by the ratio of two resistances and the constant t_1 which is the time for one cycle of the tuning fork.

Since changes in the value of the supply voltage produce like changes in i_{av} and i_{max}, the ratio of i_{av}/i_{max} remains unchanged. Variations in the power-supply voltage do not change the value of the frequency indicated.

As shown in Fig. 4, the equipment consists of two essential units, a measuring unit and a self-balancing potentiometer. The measuring unit performs the switching operations which determine the ratio of i_{av}/i_{max} while the self-balancing potentiometer measures this ratio.

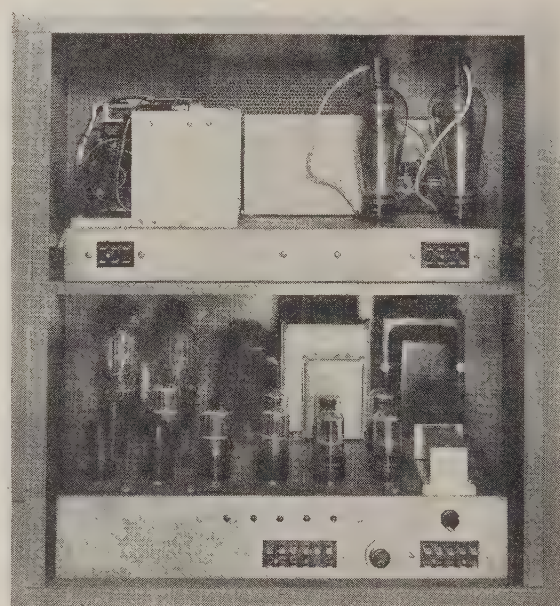

Fig. 4 Precision Tachometer

Measuring Unit

Since the required switching speed is very high, electronic instead of mechanical switches are used. To form an electronic switch two tubes are connected as shown in Fig. 5. Each tube acts as one pole of a single-pole double-throw switch, that is, only one tube conducts current at a given time. For instance, assume tube V_1, in Fig. 5, is carrying current. This current flows through R_1, causing a voltage drop. Through the voltage divider R_5 and R_6, the grid of V_2 is held so far negative with respect to its cathode that no current flows in this tube. There is no voltage drop across R_4 so that through the divider R_2 and R_3, the grid of V_1 is held positive, and V_1 continues to conduct current.

To change the switch from its original position a negative impulse may be applied to the grid of V_1 decreasing the current in V_1,

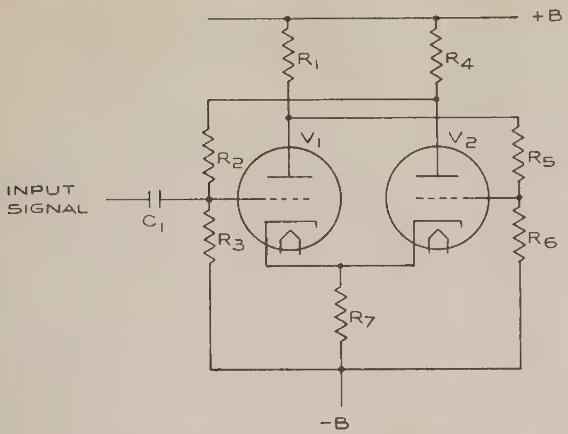

Fig. 5 Circuit of Electronic Switch

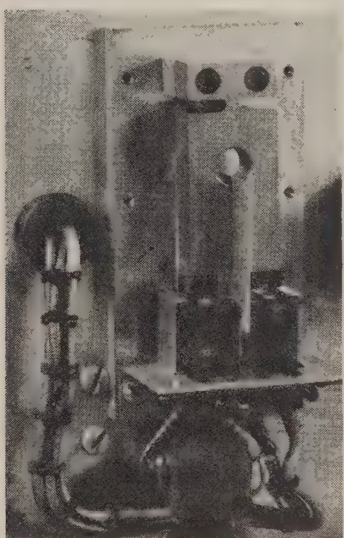

Fig. 6 Tuning Fork

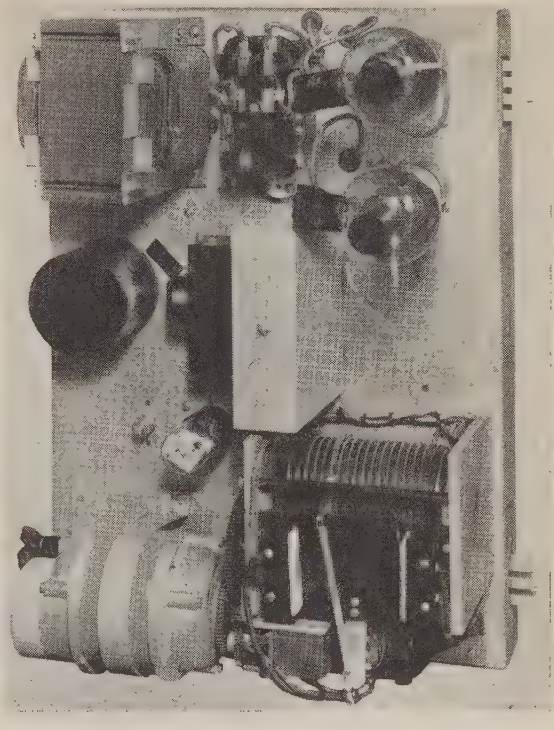

Fig. 7 Self-Balancing Potentiometer

causing its plate voltage to rise. Through the voltage divider the grid of V_2 is driven positive, causing this tube to conduct current. The resulting voltage drop across R_4 will, through the voltage divider, drive the grid of V_1 negative, thus holding off tube V_1 while tube V_2 conducts current. Thus a voltage impulse applied to one of the grids causes a transfer of current to take place similar to that of a single-pole double-throw switch.

Several of these electronic switches are used in combination to obtain the current pulses as shown in Fig. 2.

The timing element of the equipment is a tuning-fork oscillator. A close-up view of the tuning fork is shown in Fig. 6. A small Alnico magnet is mounted on the end of each tine of the tuning fork, and a coil opposite each magnet. Motion of the tuning fork generates a voltage in the coils, one of which is connected to the grid of an amplifier tube. This voltage, after being amplified, is applied to the other coil, thus sustaining the oscillations.

The frequency of the tuning fork, which is approximately 3000 cycles per sec, must in most cases be 3 times the highest frequency to be measured. Such a tuning fork can be made to provide a high degree of accuracy. The principal cause of inaccuracy is the temperature coefficient of the material. A material having a temperature coefficient of 5 parts per million per centigrade degree is used so that an accuracy of the order of 0.05 per cent is easily obtained.

Self-Balancing Potentiometer

The self-balancing potentiometer shown in Fig. 7 uses as a galvanometer an ordinary microammeter with a mirror instead of a pointer. This galvanometer reflects a beam of light from the light source to two phototubes, dividing it equally between the phototubes when the circuit is balanced. If one phototube receives more light than the other, one of the thyratrons passes current through the motor, which through a gear reduction drives the potentiometer in the direction which will bring the galvanometer to balance. The potentiometer will accurately follow variations of 2 per cent of full scale per second and has a maximum speed of 15 per cent per second. This speed is ample to follow the speed variations encountered in the application described.

The potentiometer consists of 10,000 or more turns of fine resistance wire wrapped around a core of Formex-insulated copper wire, and 14 turns of the whole wrapped around a grooved drum. A split nut carrying the slider rides in a groove so that as the drum rotates the slider follows the resistance wire. A pin on the split nut rides against a cam which is shaped so as to advance or retard the slider to compensate for nonlinearity of the resistance wire. The potentiometer unit is made accurate to 0.1 per cent or better.

Also connected to the gearing is a selsyn transmitter so that the position of the potentiometer can be transmitted to a remote location for operating the recording mechanism for indication or control. The indicating instrument shown in Fig. 8 has two hands, one of which makes 10 revolutions while the second hand indicates the number of revolutions made by the first hand. The

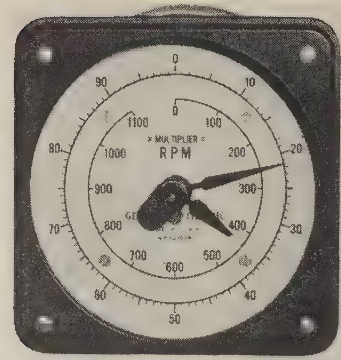

Fig. 8 Long-Scale Indicating Instrument

scale length for 10 revolutions is 86 in., making each division, which is 0.1 per cent, very nearly $^3/_{32}$ in. so that a reading to the accuracy of the equipment can be made without estimating fractions of a division. The transmitter and receiver selsyns each turn 150 revolutions for full scale so that an error of 5 deg in the selsyn, for example, would cause less than 0.01 per cent error in the indication.

Accuracy of Instrument

The method of calibration is largely responsible for the high degree of accuracy obtainable with this equipment. The known frequency of the tuning fork is connected to the input of the equipment with the circuits so arranged that one half the frequency of the tuning fork is measured. The indicating circuit is then adjusted so that the proper reading is obtained, thus correcting for any variations in the electronic circuit. Since the circuit is essentially independent of tube characteristics, these initial variations are small, and after being corrected as described, are negligible. The factors entering into the accuracy of the measuring unit then are the frequency of the tuning fork and the values of several precision resistors which are accurate to 0.05 per cent or better.

Adding up the several factors, 0.05 per cent for the tuning fork, 0.05 per cent for the resistors, and 0.1 per cent for the self-balancing potentiometer, the over-all accuracy of the device is 0.2 per cent or better.

Electromagnetic Torquemeter

By M. W. HIVELY[1] and D. F. LIVERMORE[1]

The electromagnetic torquemeter is a dynamometer of the transmission type. A calibrated shaft unit is directly connected in the rotating shaft where the torque is to be measured. This paper describes a slip-ring type of torquemeter in which the small torsional deflections in the shaft unit are measured by electromagnetic-gage elements and associated electrical components to give a continuous direct reading of torque with an accuracy of 1 per cent of full-scale torque. By proper mechanical and electrical design, effects of centrifugal forces and changes in brush resistance are held to negligible values. Several torquemeters of this type are now in use. They cover a range of 250 lb-ft at 8000 rpm to 10,000 lb-ft at 400 rpm. The same general torquemeter principle is readily applicable to much higher torque ranges.

Introduction

There is a growing demand for torquemeter equipments to measure the torque transmission through a rotating-shaft system. Some typical examples are the torque applied to an aircraft propeller or helicopter rotor, the torque transmission from a prime mover to a compressor load, and the torque transmission through drive shafts and axles in automobiles and trucks. The torquemeter will, of course, not replace the conventional cradled-dynamometer equipments which are often used for similar purposes, but nevertheless it has a very definite field of application of its own.

The torquemeter development has been going on for many years, and the various designs are almost as numerous as the development engineers who have worked in this field. Substantial progress has recently been made.

The electromagnetic torquemeter discussed herein is a transmission dynamometer of the torsion type in which a calibrated shaft unit is inserted as a section of the rotating shaft.

Most torquemeters for rotating shafting make use of the same fundamental physical principle: An elastic member, when subjected to an external torque within the elastic limit of the member, will deflect torsionally an amount proportional to the applied torque, and will return to its original state when the load is removed. The amount of angular twist in a fixed length of shaft is measured by some means. It is in this means of measuring the twist that the several types of torquemeters vary. The General Electric electromagnetic shaft unit, to which most of the discussion to follow is devoted, measures the torsional deflections, over a fixed shaft length, with electromagnetic gages. Changes in torque produce corresponding changes in the air gaps of the gages mounted in the shaft unit. These changes can be measured electrically by use of suitable electrical components which are a part of the torquemeter equipment.

Description of Electromagnetic-Torquemeter Shaft Unit

The electromagnetic torquemeter consists of the shaft unit and electrical components required to translate torsional deflections of the shaft unit into electrical-instrument readings.

The shaft unit is shown in Figs. 1 and 2. It consists of a hardened alloy-steel shaft 20 to 30 in. long which is coupled between the prime mover and the load. A section of this shaft is made with a reduced diameter so that approximately $^1/_3$ deg of torsional displacement is obtained in 2 to 4 in. of shaft length.

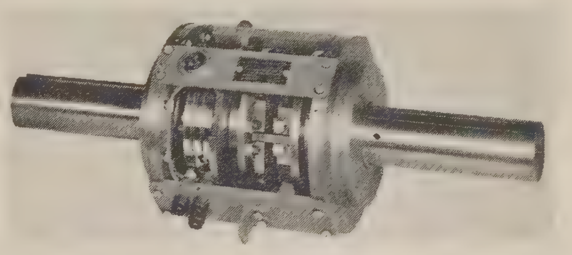

Fig. 1 Electromagnetic-Torquemeter Shaft Unit

[1] General Engineering and Consulting Laboratory, General Electric Company, Schenectady, N. Y.

Contributed by the Instruments and Regulators Division and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

A bracket fastened rigidly on one end of this section transfers this torsional displacement to the other end of the reduced section where it is measured by securely attached electromagnetic-gage elements, consisting of two U-shaped laminated cores and associated coils with an armature common to both of them. Two such brackets and gaging elements are located diametrically opposite each other with the gaging elements electrically connected together. Pure torque affects each of these elements equally. Torque and shaft-bending affect one element such that it sees a displacement which is a function of the torque, plus a displacement which is a function of bending. The other element sees a displacement which is a function of torque minus the bending effect. The two gage elements electrically average these displacements, and the bending effect in one element is canceled by an opposite effect in the other element.

A cylindrical shell spanning this reduced section of shaft and covering both gage elements is securely fastened to the shaft just beyond one end of the reduced section. A disk is securely attached to the shaft just beyond the other end of this reduced section. Both cylindrical shell and disk are notched and fitted together in such a manner that they do not touch each other until the torque is approximately 250 per cent of the maximum rating of the shaft unit. From that point on the cylindrical shell and disk carry a large part of the overload torque. This feature protects both the reduced section of shaft and the gage elements if overloads are encountered. Such overloads might occur due to sudden loading or excessive torsional oscillations. In Fig. 1 the shaft unit is shown with cover and cylindrical shell removed; however, the notched disk can be seen at the right of the slip rings.

The electrical connections to the gaging elements are made through three slip rings and two sets of brushes. Careful consideration has been given in the design of the shaft unit to minimize the effects due to variation in contact resistance between brushes and slip rings. How this is accomplished is discussed in the section entitled "Design Considerations."

Each slip ring is engaged by two brushes located 180 deg apart. The brush rigging and cover assembly is supported by end plates which are held concentric with the shaft by standard ball bearings, serving to locate the brushes in the proper axial position with respect to the shaft. The cover assembly is held stationary by a suitable anchor.

Electrical Components

The electrical components shown in Figs. 3 and 4 translate the torsional deflections as detected by the shaft-unit gaging elements into electrical-instrument readings. The shaft unit has already been described. The oscillator supplies 2000-cycle power to the torquemeter power unit which contains impedance-comparing elements. The basic circuit of the power unit and shaft unit is shown in Fig. 5. Coil 1 is located on the shaft unit diametrically opposite to coil 3. Coil 2 is adjacent to coil 1 with coil 4 diametrically opposite. When a torsional displacement increases the impedance of coil 1, it also increases the impedance of coil 3 and decreases the impedance of coils 2 and 4. These coils are connected to two capacitors $C1$ and $C2$ and to the indicating instrument through a unique rectifier arrangement as shown.

When the average impedance of coils 1 and 3 is equal to the average impedance of coils 2 and 4, there is no current flowing in the torque indicating instrument. For average impedance of 1 and 3 greater than that of 2 and 4, the current will flow in the opposite direction from that obtained when the average impedance of 1 and 3 is less than that of 2 and 4.

An electrical zero-position adjustment of the torque indicating instrument is obtained by potentiometer R. The voltmeter V is used when setting the transformer-secondary voltage at a predetermined value to give correct sensitivity.

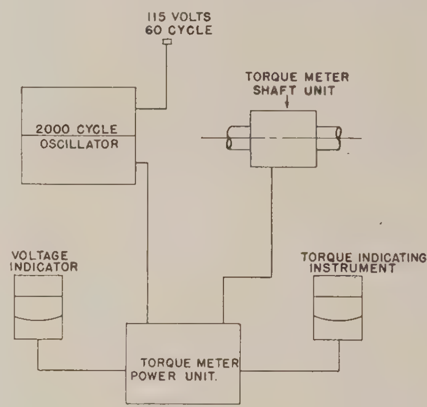

Fig. 4 Interconnection Diagram

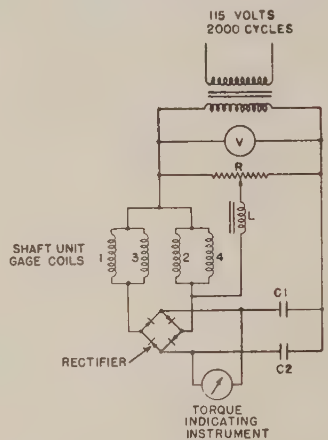

Fig. 5 Schematic Diagram of Torquemeter-Gage Circuit

The torque indicating instrument is a direct-current milliammeter with its scale marked in pound-feet of torque.

Design Considerations

Since the electrical connections to the gaging elements are made through brushes and slip rings, the contact resistance between brushes and slip rings constitutes a part of the impedance measured by the electrical components. By making the impedance of a gaging element large in comparison to the effective alternating-current resistance, the brush-contact resistance has a negligible effect on the impedance. For example, consider the vector diagram shown in Fig. 6; R, X, and Z are, respectively,

the effective alternating-current resistance, the reactance and the impedance of the gage element, including brush and lead resistances. Let ΔR be the change in R due to variations in brush-contact resistance. If ΔR is 1 per cent of the total R, Z is changed by 1 per cent for $\theta = 0$, by 0.65 per cent for $\theta = 30$ deg, by 0.25 per cent for $\theta = 60$ deg, and by approximately zero per cent for $\theta = 90$ deg.

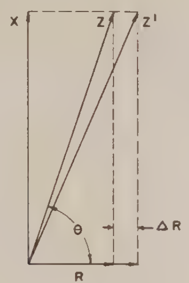

FIG. 6 VECTOR DIAGRAM OF GAGE ELEMENT

A value of θ close to 80 deg is obtained by use of laminated cores and armatures of very good magnetic properties, the use of coils with a large number of turns, and the use of 2000-cycle excitation. At 80 deg a 1 per cent change in total resistance produces only 0.04 per cent change in impedance. The electric circuit used compares impedances independent of phase angles. Since an impedance differential of 40 per cent is obtained at 100 per cent torque, this 0.04 per cent change in impedance due to 1 per cent resistance change will produce only 0.1 per cent change in torque reading. The variation in brush resistance observed under normal operating conditions is from 1 to 2 per cent of the total resistance. This small change in brush-contact resistance is obtained by using silver slip rings and graphite brushes.

Variation in brush resistance was found to increase somewhat with increased slip-ring surface speed. While a sharp line cannot be drawn as to the limiting speed to be tolerated, it has been found desirable to keep the slip-ring peripheral speeds at 80 fps or less.

The action of centrifugal forces on the gage elements is also an important consideration. Gage coils and laminations must be supported rigidly and strongly: (1) to hold the gages in place and (2) to prevent centrifugal forces from displacing the gage elements in a manner which would produce a drift in torquemeter readings as a function of speed. The particular unit shown in Fig. 1 has been run at speeds over 5000 rpm without encountering difficulties from centrifugal effects. A torquemeter of the same general type has successfully been run at 8000 rpm. This was accomplished by a more rigid gage-element supporting structure and by using small slip rings.

Over-All Performance

In general, an accuracy of 1 per cent and a repetitive accuracy of 0.5 per cent of full-scale torque can be expected with the electromagnetic torquemeter described in this paper. Tests made using a cradled dynamometer to calibrate the shaft unit at operating speeds show that static calibrations agree so closely with dynamic calibrations that only static calibrations are needed. A typical calibration curve is shown in Fig. 7. The calibration is seen to be very linear except for a slight deviation at full torque. When best accuracy is required, corrections obtained from calibration data should be applied to the torquemeter readings.

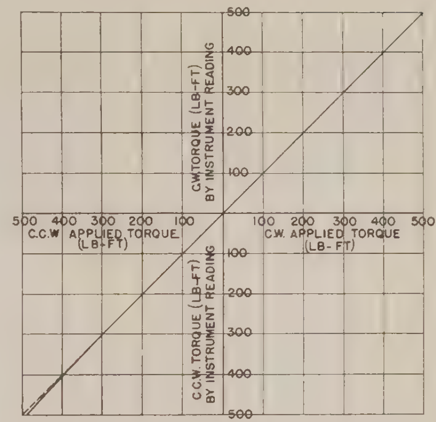

FIG. 7 CALIBRATION CURVE FOR SHAFT UNIT RATED AT 500 LB-FT MAXIMUM TORQUE

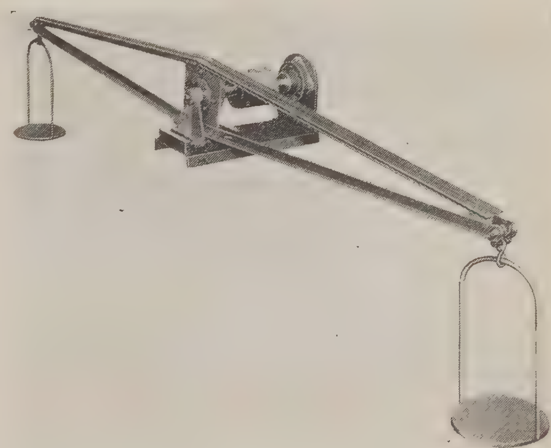

FIG. 8 STATIC CALIBRATING STAND

Calibration

Fig. 8 shows a static calibrating stand with a shaft unit bolted by the attached half-couplings to a fixed plate on one end of the calibrating stand and a pivoted torque arm on the other, through which a known load is applied by adding standard weights to the weight pans hanging from knife-edges at the ends of the arm. The knife-edges provide an accurate loading point, and the ball-bearing central pivot supports the applied weights and provides a nearly frictionless pivot, making it possible to apply an accurately known torque. Thus very accurate calibrations can be obtained.

Applications

The operation of electromagnetic torquemeters now in practical use has proved to be very satisfactory. The torque and speed ranges covered by these torquemeters extend from 250 lb-ft at 8000 rpm to 10,000 lb-ft at 400 rpm. These ranges are by no means considered as limits for electromagnetic torquemeters.

Modern trends in the design of rotating equipment are toward lightweight with accompanying high stresses. Therefore it becomes not only desirable but essential, in many cases, to know just what torque is being delivered through a section of shafting.

In addition to the torque instrument reading obtained, the torquemeter output may be used with electronic control equipment for regulating the torque delivered by a rotating shaft.

Someday torquemeters of one type or another will be standard equipment in large aircraft, on ships, and many other places where rotating shafts are used to transmit power. For the present, however, torquemeters will likely find their greatest use in production-test setups where comparative data are needed to standardize a product, or in research and development test installations where they can be used to obtain data useful in improving the design of a product.

Discussion

J. G. Fleming.[2] It is suggested that the following points discussed by the authors might be further clarified:

1 An accuracy of 1 per cent of full scale is cited in the paper. How long can this accuracy be maintained under normal operating conditions without rechecking for calibration and zero stability?

2 What is the speed of response of this instrument?

3 The application of the electromagnetic torquemeter for large-aircraft use is cited in the paper. How compact would the instrument be and what would be its approximate weight and cost for application with aircraft engines rated at approximately 1000 hp?

4 It is stated that the slip-ring contact resistance is very small compared to the circuit resistance and that therefore variations in slip-ring resistance do not affect the instrument operation. Fig. 5 of the paper indicates that the output is fed into a rectifier bridge which operates a galvanometer. The resistance of such rectifiers is usually quite large and undoubtedly much larger than the slip-ring contact resistance. The resistance of rectifiers increases on aging, and it appears that such a change would cause a gradual calibration drift. A bridge of this type could be operated with a null-balance galvanometer which would make the measuring circuit free from changes in resistance in the rectifiers.

N. S. Muir.[3] The writer wishes to confirm the authors' belief that the application of electromagnetic principles to the measurement of torque can provide a very satisfactory method capable of wide application in various mechanical systems. The authors may be interested in learning something about a similar application of the electromagnetic principle in a transmission dynamometer developed at the Royal Aircraft Establishment in England about 13 years ago which aimed at giving an accurate record of the mean torque transmitted by an aircraft engine to a propeller.

The research which preceded the development and construction of this particular torquemeter was initiated by the British Air Ministry early in 1930, aiming at the evolution of a satisfactory transmission dynamometer for the measurement of engine power in flight and in the then proposed 24-ft wind tunnel. From a critical discussion of the available methods as one would employ them in a practical transmission dynamometer, it was decided that the variable-air-gap method would provide a basic arrangement which would be favorable compared with the others, such as piezoelectric crystals, capacity units, resistance-pressure elements, etc.

One of the main features of the electromagnetic system in common with that of a capacity unit is that no direct connection need exist between the two moving members other than the flexible element providing the desired relationship between force and deflection. The line of attack chosen therefore for the research was the construction of a torquemeter in which the angular deflection of a spring element inserted in the drive between an engine and airscrew would be measured by electrical means, using variable air gaps. Thus we had two of the time-honored foundations for the transmission dynamometer design being remolded and combined in the light of modern knowledge of the application of scientific principles and the use of new materials. The basis of the electrical system chosen was attributable to Ford and may be described briefly as one in which the electromotive force (emf) due to change of inductance of a transformer secondary coil, consequent upon a change of air gap in an adjacent iron circuit forming the core, is balanced by an equal and opposite emf generated in a remotely situated receiver having a similar circuit operated by hand.

In the torquemeter being described, the deflection of the spring element was arranged to vary the air gaps in the system specially developed for the purpose, and an electrical balance was obtained by means of a micrometer-screw device on the receiver; the balanced position of the air gaps being read off a scale attached to the screw as in the Ford torsion meter. The null-reading condition of electrical balance is indicated by a moving-coil current-measuring instrument of adequate sensitivity. When forced torsional oscillations are present in the drive, the air gaps vary cyclically about the mean value, and the true mean deflection is still readable in terms of electrical balance of the moving-coil instrument, the mechanism of which is then suitably damped.

In the earlier air-gap instruments of Denny, Ford, and Moullin, the systems were energized from small alternators or by interrupted direct current of relatively low frequency. This latest unit to which reference is made is fed from a special 1500-cycle alternator designed to have a purely sinusoidal voltage output. The high frequency is essential to deal with the presence of torque oscillations in the airscrew drives in aero engines up to about 200 per sec, so that integration of the torque variation may be sufficiently accurate.

The basic design for our first torquemeter was completed in March, 1930, and the apparatus was ready for calibration in May, 1931. Preliminary experience was gained with this first unit, covering some 70 or 80 hr running on the test bench on a Jupiter VII supercharged direct-drive engine and using the Froude brake as the criterion of torque. At constant speeds, accuracy within 0.3 per cent was obtained, while over a range of speeds the greatest error was within 2 per cent. The apparatus was then transferred to an aircraft and successful use in flight was achieved. Special apparatus was provided to obtain an accurate measure of the rotational speed of the engine, since the computation of horsepower depends upon the product of speed and torque.

A second unit was provided primarily for use in the then proposed 24-ft wind tunnel at Farnborough to enable full-scale testing of propellers to be carried out. In this case the spring element took the form of a one-piece wheel in which the rim, spokes, and hub were carved out of a solid disk of about 18 to 20 in. diam and was capable, in conjunction with the electrical system, of giving readings of torque over a wide range from one-quarter to full torque of engines up to about 1000 hp.

It will be appreciated that the null-reading electrical system chosen is not the same as that described in the paper just presented, which uses an electrical system on the lines of that used by Moullin, where the output of an alternator or 2000-cycle oscillator is modulated by the torquemeter coils to give a direct rectified indication of torque. At an early stage of our investigation it was found essential to have an especially accurate apparatus for carrying out static-torque calibrations, and a tackle was

[2] The Bristol Company, Waterbury, Conn.

[3] Chief, Engine Development Section, British Supply and Air Commission, Washington, D. C.

specially designed for the purpose, which permitted the rolling load of a beam system to impose pure torques on the shaft carrying the torquemeter so that positive and negative torques could be smoothly applied according to the direction of motion of the load from the central position of no torque. The apparatus has ball bearings at every moving joint and is extremely delicate in its operation; torques of only 2 or 3 lb-in. being accurately obtained.

Limit stops were provided on the spring element which permitted a range of torque of from 60,000 lb-in. to approximately —12,000 lb-in. and some idea of the accuracy of the spring element in maintaining its zero at no torque is given by the fact that after taking the spring through several cycles of stress on the torque loading elements previously mentioned to remove any slight hysteresis in the material and then determine its zero setting, it returned after subsequent cycles of stress to this zero position within 1/40,000 in. at 9.625 in. radius. This radius refers to the position of a dial-gage reading to 1/10,000 in. which was attached in such a way as to record this circumferential deflection of the spring as it deflected. This dynamometer was used satisfactorily in large 24-ft wind tunnel at Farnborough for the measurement of torque in full-scale propellers.

Many applications of such a system can be made, and a dynamometer of this type lends itself to use either as a transmission coupling or as a static unit mounted in conjunction with aero-engine reduction gears or in any position where the torque to be measured reacts on a stationary member. From the writer's experience with this torquemeter, assurance can be given to the authors that their application is well worth development along the lines which they propose and for the applications which they mention. The writer's opinion, however, is that a null-reading system is much more likely to give enhanced accuracy than the use merely of the output from an unbalanced coil system. One important feature which must not be overlooked is, as previously stated, the accurate calibration of the spring element whether it be a piece of shaft or actual springs. This, in fact, is particularly important where in measurement on ship's propeller shafts a relatively long length of shaft is chosen. The writer agrees with the authors' attention to the slip rings and brushes used in the system. In the British torquemeter which the writer has just described, we have recently redesigned the recording circuit so as to eliminate completely any errors arising from faulty slip-ring contacts.

Author's Closure

Mr. Fleming brings up several points which will be discussed briefly in order.

(1) The electromagnetic torquemeter described should maintain its calibration. However, the zero adjustment may have to be made occasionally and should be checked whenever possible.

(2) The speed of response is limited by the indicating instrument and is approximately two seconds. A magnetic oscillograph may be used in place of the indicating instrument to record rapid torque variations up to several hundred cycles per second.

(3) The electromagnetic torquemeters described in the paper are not suitable for general flight applications on aircraft engines.

(4) The resistance of the rectifier section is approximately 20 ohms which is small in the light of the several hundred ohm gage circuit impedances. The advantages of a null system are recognized and are frequently put to good use. A continuous indicating system has the advantage of convenience over a null system where the balancing must be done manually. Accurate automatic null balancing systems are available.

Taking the Mystery Out of the Kadenacy System of Scavenging Diesel Engines

By P. H. SCHWEITZER,[1] C. W. VAN OVERBEKE,[2] and L. MANSON[3]

The "Kadenacy effect" of the Diesel-engine exhaust is utilized to create a vacuum in the cylinder for introducing the fresh charge. The result of the application of this system is exemplified in tests in 1939, of a converted Junkers opposed-piston engine in which the power was raised from 11 to 25 hp, or an increase of 130 per cent. This was accomplished solely by changing the characteristics of the inlet and exhaust ports and passages in accordance with the Kadenacy patents. However, the theory expounded by the inventor has been subject to question, as the authors explain, and while the results are entirely matters of record, the phenomenon can be accounted for by conventional thermodynamics based upon simple adiabatic expansion. This fact the authors have demonstrated by experiment. The formulas derived check closely with those of Kadenacy but they are based upon a more rational approach to the problem than Kadenacy's contention that supersonic velocities are involved in the exhaust process.

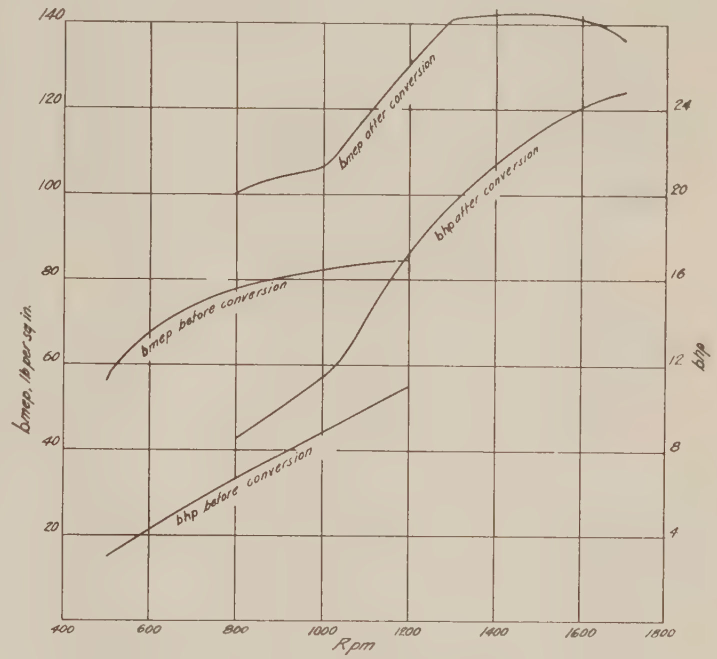

Fig. 1 Horsepower and Brake Mean Effective Pressure of Junkers Opposed-Piston Engine Before and After Conversion to Kadenacy System

During the last few years the Kadenacy system of scavenging Diesel engines has attracted some attention in this country and more abroad. That system is best known in the form of a blowerless two-stroke-cycle engine. The "Kadenacy effect" of the exhaust is utilized to create a vacuum in the cylinder for introducing the fresh charge. That by itself would not be remarkable if we were to attribute the effect to a tuned exhaust pipe. The Kadenacy system, however, embraces more than that. In numerous patents (1)[4] an ever-recurring sentence is that "at least a substantial portion of the burnt gases leaves the cylinder at a speed much higher than that obtaining when a flow resulting from an adiabatic expansion only is involved, and in such a short interval of time that it is discharged as a mass, leaving a depression behind it which is utilized in introducing a fresh charge into the cylinder, etc." This has been quoted from U. S. Patent 2,168,528. Kadenacy's other patents include various versions of the same statement and explain that mass means a "coherent mass" (Patent No. 2,123,569), "having properties similar to those of a resilient body" (Patent No. 2,102,559), and that the "ballistic" speeds involved in the evacuation are about 4 times higher than "the speed of adiabatic expansion," leaving behind them "a high depression which may reach a complete vacuum" (Patent No. 2,131,957).

The foregoing notions are so unorthodox that many engineers ignored and even ridiculed them. But it is not wise to ignore test results and Kadenacy has astonishing results to his credit.

The first commercial blowerless Kadenacy engine was built by Petter (2), and the same company is still building Kadenacy-type engines of an improved design (3); however, with a blower attached.

According to tests (4), described in 1939, the conversion of a Junkers opposed-piston engine resulted in a substantial increase of power. Some test results are reproduced in Fig. 1. The maximum power was raised from about 11 to 25 hp, an increase of 130 per cent. This is claimed to have been obtained without any alteration to the combustion chamber or fuel-injection equipment, solely by changing the characteristics of the inlet and exhaust ports and passages, in accordance with the Kadenacy patents. The scavenge pump was rendered inoperative and the inlet ports, which were still controlled by the upper piston, were arranged so that they communicated directly with the atmosphere. With the Kadenacy system fitted to the engine it was possible to run the engine to a much higher speed without any ill effects, it is claimed. The pistons remained in a cooler condition, the maxi-

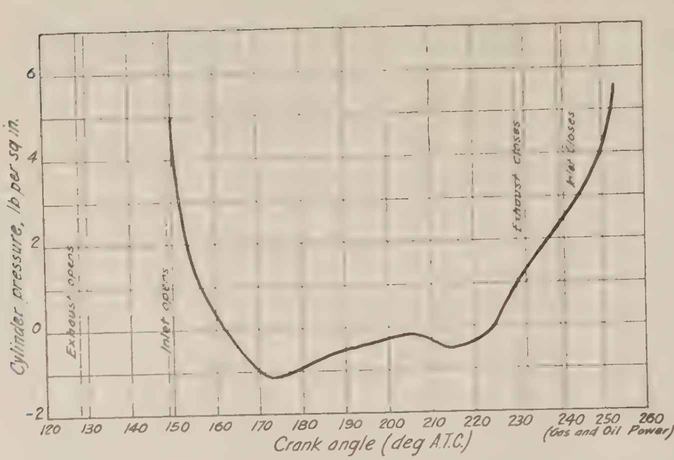

FIG. 2 CYLINDER PRESSURES IN THE JUNKERS-KADENACY OPPOSED-PISTON ENGINE

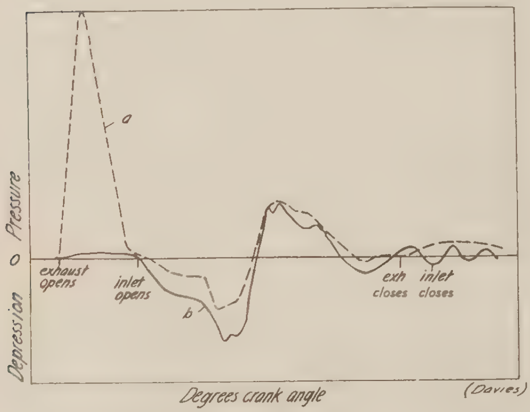

FIG. 3 PRESSURE FLUCTUATIONS IN EXHAUST DUCT—LINE A—AND INLET DUCT—LINE B—OF A JUNKERS-KADENACY ENGINE; 650 RPM

mum pressures were lower and the specific fuel consumption also was lower.

Fig. 2 shows the cylinder pressures in the Kadenacy-Junkers engine operating without scavenging air pump. It is notable that a depression over 1 psi below atmospheric occurred in the cylinder 50 deg after the exhaust ports had opened.

Fig. 3 shows the pressures in the intake and exhaust ducts of the converted Junkers engine from which it is seen that pressure changes are transmitted from the exhaust ducts to the intake ducts without appreciable delay. Tests at 800 rpm with various lengths of exhaust pipes gave Fig. 4 which shows that the Kadenacy effect does not depend upon a particular pipe length, only the time of maximum depression was retarded when the exhaust-pipe length was increased.

We have dwelt on this Kadenacy-Junkers engine because part of the tests reported were made by such an unquestioned authority as Prof. S. J. Davies of London, England.

Conversions of other two-stroke engines of either uniflow or the cross-scavenge type gave similar results, although not quite as spectacular as those shown in Fig. 1. Some engines fitted with the Kadenacy system had blowers and others had none. When a blower was used the scavenge-air pressure was considerably less, and significantly it decreased when the load increased. In the original engine the scavenging pressure increased with the load. The difference is explained by the fact that with the Kadenacy system as the load becomes greater the energy in the exhaust also becomes greater and with it the suction effect in the cylinder, thus reducing the resistance to the delivery of the air from the blower. Converted engines consistently showed appreciable power increase with lower specific fuel consumption and lower exhaust temperatures.

The mechanics of the Kadenacy principle were investigated by Davies (5) with a free-moving piston in a cylinder. He compressed a mixture of air and gasoline vapor with a hand crank and ignited it with a spark plug. The gas pressure sent the piston downward until it uncovered a slot through which the burnt gases discharged into the atmosphere. This sudden discharge caused so great a depression in the cylinder that the free piston rose in the cylinder and came to rest at about two thirds of its upward travel. With photoelectric apparatus, Davies recorded the piston travel and showed that the entire process was completed in a very short time. With a cylinder of 2.4 in. bore and 2.2 in. effective stroke the exhaust process lasted only 3.2 milliseconds and the residual depression was 17 in. Hg abs. Experiments with various lengths of exhaust pipes showed that the resulting depression and the time during which the exhaust slot remained uncovered were largely unaffected by the exhaust pipe. For instance, when the exhaust-pipe length was changed from 7.5 to 53 in., the duration of the exhaust period changed only about 6 per cent. The gas flow in the exhaust pipe was shown by high-speed photography of a lightweight "cursor" in a glass exhaust pipe. This revealed a very rapid back-and-forth movement of the gas column.

While the results obtained with the Kadenacy system are fully discussed in the literature, the constructional details are not disclosed. One or more of the expedients shown in the patent drawings such as tapered exhaust pipes and reflection-wave stoppers might have been employed to obtain the excellent results but apparently no particular importance is attached to them.

In view of these reports, the authors felt a necessity to de-

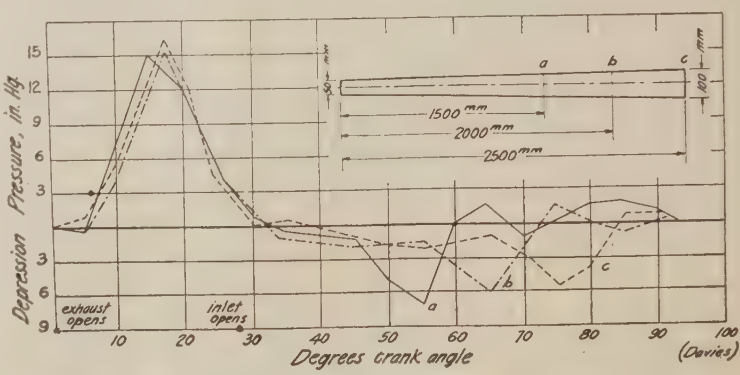

FIG. 4 PRESSURES IN EXHAUST PIPE OF JUNKERS-KADENACY ENGINE WITH VARIOUS LENGTHS OF EXHAUST PIPES; 800 RPM

termine in a conclusive manner whether the so-called Kadenacy effect really exists, aside from the pipe effect the nature of which is fairly well known (6).

Investigation of the Kadenacy Effect

Kadenacy claims that upon opening the exhaust port the gas leaving the cylinder with a very high (supersonic) velocity will evacuate it, leaving a partial or complete void behind, irrespective of whether a pipe is attached to the cylinder or not.

The depression thus created in a cylinder, no matter how short in duration, can be measured and no combustion needs to be involved in the test.

In order to measure the depression following a sudden gas outflow, a special setup was built at The Pennsylvania State College. It consists of a steel cylinder, Fig. 5, closed by a lid locked with a quick-acting latch. This lid is forced open by the initial cylinder pressure when the latch is released. Orifices of different diameters or nozzles were fixed at the lid end of the cylinder. A pickup for determining the lowest pressure reached in the cylinder during the exhaust was fixed at the closed end of the cylinder. This pickup consists of a brass diaphragm of $2^1/_4$ in. diam and 0.025 in. thick, exposed to the cylinder pressure on one side, and to an adjustable depression on the other. The diaphragm opens an electric contact when the pressure in the cylinder drops below the adjusted depression; the contact is inserted in a 6-volt circuit in series with a transformer coil. A neon lamp is placed in series with the secondary winding of the transformer. This gives a flash when the primary circuit opens.

The depressions have been measured for different orifice diameters and different initial tank pressures. The results are shown in Fig. 6 where the maximum depression after the gases have rushed out of the cylinder, are plotted against the cylinder gage pressure before the cylinder was opened. With the 6-in. orifice there was in effect no plate, as the cylinder was wide open. One curve corresponds to the use of a convergent-divergent nozzle with 2-in. throat diameter and $3^1/_8$-in. length. The opening on the pressure side was $4^1/_2$ in. and convergence took place for 2 in. Over the remaining $1^1/_8$ in. the nozzle diverged uniformly at an angle of 15 deg.

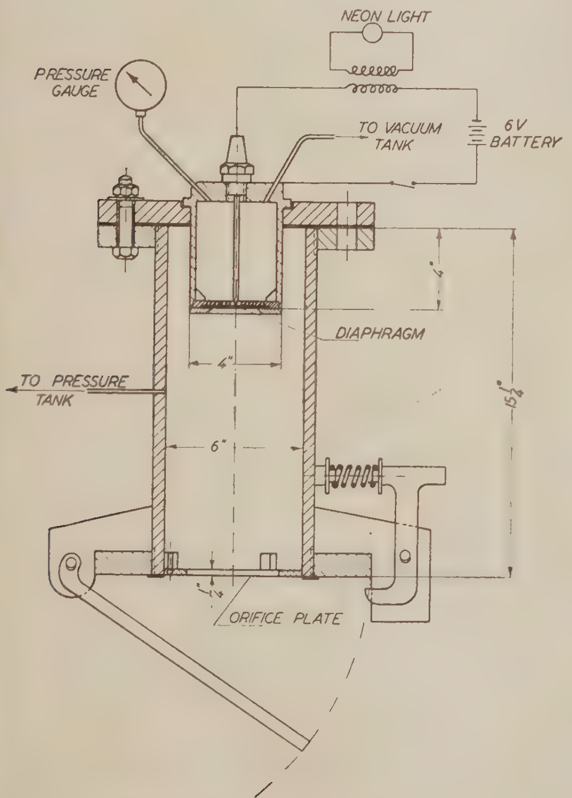

Fig. 5 Vessel With Quick-Opening Lid to Test Kadenacy Effect

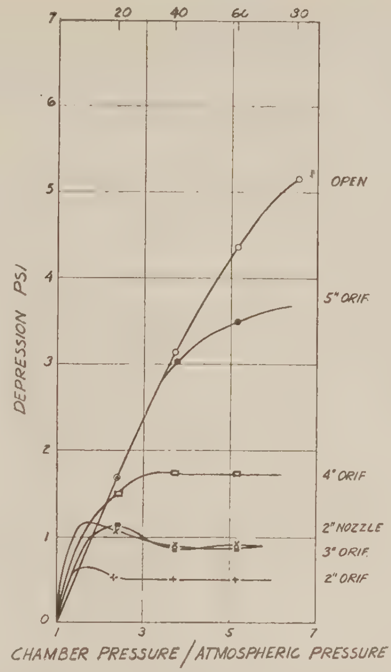

Fig. 6 Kadenacy Effect; Observed Depressions by Sudden Pressure Release, Penn State Experiments

The experiments show that the depression, although far from a complete void, is great enough to account for the results on two-stroke Diesel engines applying Kadenacy's patents.

Theory of the Kadenacy Effect

Various explanations of the Kadenacy effect have been published. Giffen (7) calculated the pressure waves generated by the sudden evacuation of a cylindrical vessel and obtained depressions of the order that we have observed. His calculations even showed that with an orifice appreciably smaller than the cylinder the depression does not increase continuously with the increase of the initial cylinder pressure but it reaches a maximum when the initial cylinder pressure is around 20 psia, and if it exceeds that, the depression begins to decrease. This agrees with our observations with orifices and nozzles of 3 in. diam or smaller.

Geyer (8) proposed a rather simple theory of the Kadenacy effect. He attributes the evacuation of the cylinder to the kinetic energy of the gases still in the cylinder, yet rushing out of the cylinder.

It is not improbable that Geyer got the idea for his theory from Kadenacy himself. For instance, in U. S. Patent No. 2,123,569, Kadenacy is using the analogy of a coil spring to explain what happens in the cylinder. He visualizes a helical spring on a table compressed, with a certain amount of energy

stored in it. If the spring is released gradually by allowing it to expand against a resistance, it will return to its free length. The work done by the spring will then become stored in the resistance. This, he states, corresponds to the release of compressed gases from a container through an orifice which is opened gradually.

On the other hand, if the spring, after having been compressed on the table, is released suddenly by removing the compressing means in a short interval of time, the spring while expanding will leave the table bodily. The energy stored in the spring imparts momentum to the spring. During its flight through the air after it has left the table, oscillations will occur in the spring but these oscillations will bear no direct relation with the motion of the spring body from the table. This case corresponds to the sudden release of the gas from the cylinder according to Kadenacy.

Geyer goes through a somewhat similar reasoning. The potential energy of the compressed gas is transformed into kinetic energy. The gas will leave the cylinder with a velocity that corresponds to this energy. At the time the pressure inside of the cylinder has dropped to atmospheric, the gas in the cylinder still has some kinetic energy, which will perform work against the atmospheric pressure. This work consists of displacing a certain volume of air against ambient pressure. The equivalent volume of air to replace the volume must come from the cylinder, and so a depression is created by the discharge of that amount of air.

Geyer's simple theory can have no pretension of describing accurately such a complex phenomenon as the sudden evacuation of a cylinder. Yet it not only gives a correct mental picture of the mechanism of the Kadenacy effect but surprisingly it even gives tolerable agreement with observed results. Geyer has applied his calculations to Davies' experiments (8), and we to the Penn State experiments (9), which are shown in Fig. 7.

In Fig. 8 is reproduced a comparison of the observed and calculated depressions when the sudden removal of the lid uncovered the full cylinder opening. With smaller orifices the observed depressions are higher than those calculated.

Ballistic Velocities

A recurrent statement in most Kadenacy patents is that the burnt gases discharge through the exhaust ports at a speed far in excess of the speed of adiabatic expansion. Patent No. 2,123,569 gives the "speed of adiabatic expansion" as 350 to 450 m per sec, and gives the "ballistic speed" of exhaust due to the "ballistic force" as 1400 to 1800 m per sec, that is about 4 times as high.

The velocity of sound in a diatomic gas of a temperature about equal to that of the exhaust gases is as a matter of fact 350 to 450 m per sec. In a straight or convergent orifice this is also the upper limit of discharge velocity of the gas.

The authors were unable to find out where figures of 1400 to 1800 m per sec had been obtained. But Kadancy uses these figures in porting design and obtains good results. This may be an indirect proof that his figures are correct. Let us examine this evidence.

Since the pressure in the cylinder when the exhaust port opens is about 5 atm, Kadenacy reasons, 4 volumes of exhaust gases have to be discharged to bring the pressure down to atmospheric during the blowdown period. It takes, he states, as much time to discharge 4 cylinder volumes of gas at 1800 m per sec velocity as one volume of gas at $^1/_4 \times 1800 = 450$ m per sec velocity. Therefore he envisages the "hypothetical velocity" of 450 m per sec and designs his exhaust ports in such a manner that the gas column which projects through the exhaust port during the exhaust-lead period with the hypothetical velocity of 450 m per sec, is just equal to 1 cylinder volume. If V denotes this volume in cubic meters, A_m the mean uncovered exhaust-port area during

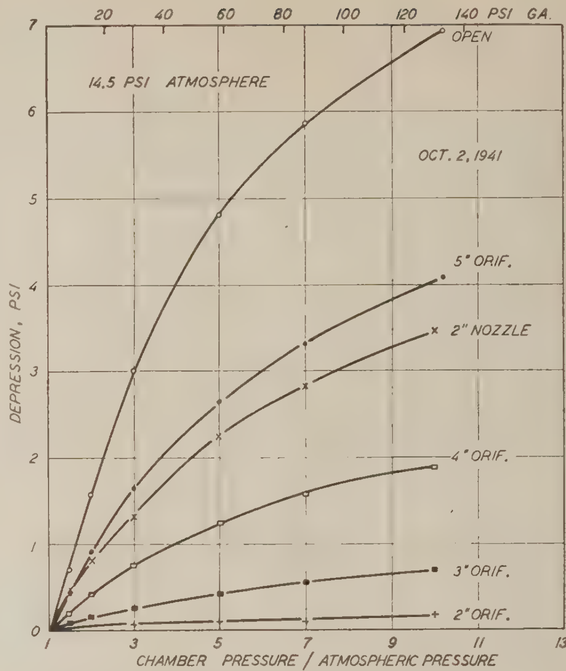

Fig. 7 Kadenacy Effect; Geyer's Theory Applied to Penn State Experiments

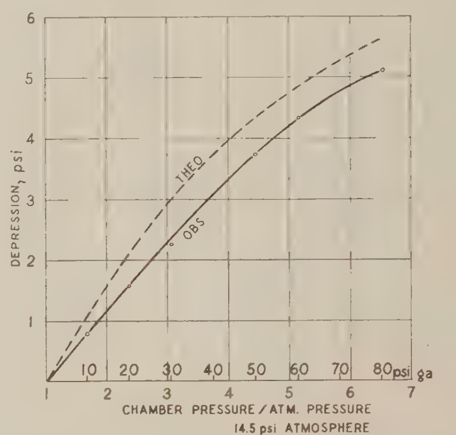

Fig. 8 Kadenacy Effect; Observed and Calculated Depressions; Open End

the exhaust lead (blowdown period) in square meters, and L the length of the hypothetical gas column in meters, then

$$V = A_m L \qquad [1]$$

the hypothetical velocity which is 450 m per sec, is given by

$$V_{hyp} = \frac{L}{t} \qquad [2]$$

where t is the time of the blowdown period in seconds, and

$$t = \frac{\alpha}{6n} \qquad [3]$$

Here α is the exhaust lead in degrees and n is the engine speed in revolutions per minute.

From Equations [1], [2], and [3]

$$V = A_m \, V_{\text{hyp}} \frac{\alpha}{6n} \ldots\ldots\ldots\ldots [4]$$

Putting $V_{\text{hyp}} = 450$ and rearranging, we get

$$A_m \alpha = V n \frac{6}{450} = \frac{V n}{75} \quad m^2 \text{ deg} \ldots\ldots\ldots [5]$$

This is Kadenacy's reasoning, and the resulting formula is identical with Kadenacy's formula Patent No. 2,144,065

$$\frac{W}{100\, KA} = \frac{a}{360\, N} = t$$

except for the different symbols. From this the proper exhaust lead can be calculated. By converting the metric units used in Kadenacy's Equation [5] to square inches we get

$$A_m \alpha = \frac{(39.4)^2}{(39.4)^3} \frac{Vn}{75} = 0.00034 \; Vn \ldots\ldots\ldots [6]$$

This is still Kadenacy's formula in a slightly changed form. On the other hand Schweitzer's formula (10) gives

$$A_m \alpha = 0.00033 \; V_{\text{disp}} n \ldots\ldots\ldots\ldots [7]$$

Ignoring the difference between V and V_{disp}, Equation [7] differs only 3 per cent from Equation [6].

Equation [6] is a consequence of the Kadenacy theory, but Equation [7] was derived independently of the Kadenacy theory, before we knew of the latter's existence. The Kadenacy theory supposes the existence of "ballistic velocities" which are about 4 times higher than those obtained from adiabatic expansion. Equation [7] was derived by conventional thermodynamics, and the discharge velocities used were substantially the same as sound velocities modified by discharge coefficients obtained by the Nusselt theory. The two theories give practically identical results.

The circumstance that Kadenacy got correct results from incorrect premises casts a doubt on Kadenacy's reasoning.

We believe Kadenacy's reasoning to be fallacious and in the following we try to show the error in it.

Fallacy in Kadenacy Theory

Kadenacy states[5] that instead of applying the true ballistic velocity, 1800 m per sec to 4 cylinder volumes of gases to bring down the pressure from 5 atm to 1 atm, one may use a hypothetical velocity of 1800/4 = 450 m per sec to 1 cylinder volume and get the same results. We believe this to be a mistake. One cylinder volume should be considered and not 4, even if the pressure in the cylinder is 5 atm.

A rough reasoning should suffice to make this clear. Let us consider two cases. In one case the density of the gas does not vary during the discharge. Before, in, and after the exhaust orifice, the density is the same. In this case (which is analogous to the discharge of water) if the cylinder volume V contains gas at 5 atm pressure and that is discharged through an orifice A with 450 m per sec discharge velocity, and $A = V/450$, then at the end of 1 sec all of the gas will be discharged and not $^1/_5$ of it only. It makes no difference whether the pressure in the cylinder was 5, 4, 3, 2, or 1 atm. In every case 450 m per sec discharge velocity is required to evacuate the cylinder in 1 sec. The assumption of a ballistic velocity of 1800 m per sec is unjustified.

[5] U. S. Patent No. 2,123,569, p. 4, lines 33–62.

Let us next consider the change in gas density. The discharge velocity refers to the throat of the orifice, and the specific weight to be considered is the one existing in the throat.

Calculation by conventional thermodynamics shows that the specific weight in the throat is approximately 0.78 kg per cu m in the beginning of the blowdown and drops gradually to approximately 0.4 kg per cu m at the end. Assuming a constant discharge velocity of 450 m per sec and a constant exhaust orifice of Am^2 during the t sec of the blowdown period, we shall discharge

$$450 \, \frac{0.78 + 0.4}{2} \, A \text{ kg of air}$$

If, conforming to Kadenacy, we make $A = V/450$, where V is the total cylinder volume, the amount discharged will be

$$D = 0.59 \; V \text{ kg}$$

while the amount that has to be discharged to drop the pressure from 5 atm to 1 atm is

$$D_1 = \frac{4}{5} V \gamma_{\text{int}} = 0.8 \; V \; 0.73 = 0.585 \; V \text{ kg}$$

It is seen that D approximately equals D_1, which means the exhaust can be disposed of in the required time period, assuming only sound velocity and no supersonic or ballistic velocity is required.

We conclude that while the value of Kadenacy's hypothetical velocity is sound and should give good results if applied to porting design, it in no way supports the existence of ballistic velocities in excess of sound velocities.

A further confirmation of this conclusion can be found in calculating from Geyer's theory the outflow velocities created by the sudden opening of an air-filled vessel. Fig. 9 shows these velocities, and for comparison, also the calculated sound velocities for various temperatures. For the detailed calculation the reader is

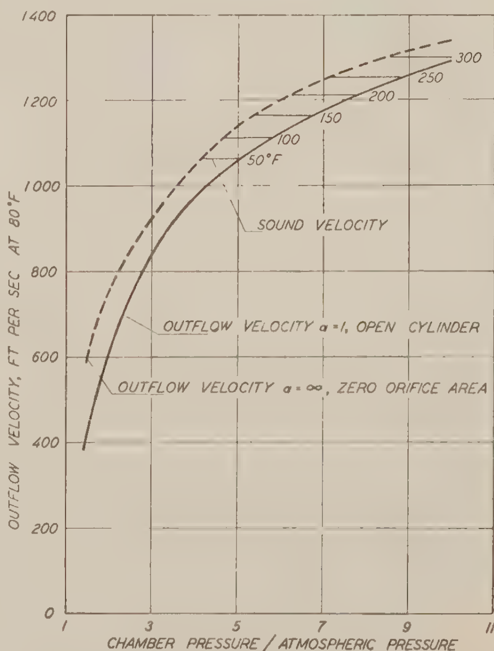

Fig. 9 Outflow Velocities Created by Sudden Opening of Vessel Filled With Air, From Geyer's Theory

referred to (9). An inspection of Fig. 9 reveals that with 5 to 7 atm chamber pressure the outflow velocities do not differ much from the sound velocities.

Conclusions

1 The astonishing performance claimed by Kadenacy engines should not be rejected as incredible as the effect is based upon a demonstrable physical phenomenon; the rarefaction that follows the sudden discharge of compressed gas from a closed vessel.

2 The Kadenacy effect is not due solely to the inertia of the gas column in the exhaust pipe, as 10 in. Hg depression was observed by the authors in a vessel without any exhaust pipe, and reported results show good performance in engines with varying lengths of exhaust pipes.

3 The Kadenacy effect vanishes if the discharge opening becomes relatively small. One inference is that an obstacle of the full exploitation of the Kadenacy effect is that exhaust ports or valves in engines cannot be opened rapidly enough.

4 Geyer's theory seems to give a fair picture of the mechanics of the Kadenacy effect and excellent numerical agreement in case of a large discharge opening.

5 Nothing in our observations supports Kadenacy's contention that velocities in excess of sound velocities are involved in the exhaust process. Conventional thermodynamics based upon simple adiabatic expansion gave formulas practically identical with those recommended by Kadenacy, and Geyer's theory applied to our experiments also successfully indicated discharge velocities of the order of sound velocities and no higher.

Discussion

Paul Diserens.[6] The authors' discussion of the Kadenacy effect is particularly timely in view of the development of two-cycle engines, sponsored by Mr. Kadenacy, on the part of several American manufacturers at this time.

It would appear that the paper is, in effect, a continuation of the extended discussion of the Kadenacy engine which was reported in the British and the Continental technical press during the years 1938 to 1941, inclusive. While the authors make some reference to the numerous articles published at that time, it might be suggested that a bibliography comprising the more important references would constitute a valuable addition to the paper.

The writer finds it of particular interest to compare the apparatus used by the authors in their experiments, with that employed by Prof. S. J. Davies, of Kings College, University of London.[7]

It should be noted that in the Davies apparatus provision is made to insure the greatest possible speed in establishing communication between the pressure vessel and the atmosphere. In the apparatus used by the authors the speed of opening is limited because of the time required to accelerate the communicating valve.

It is evident that the results reported in the paper reflect the influence attributable to the speed of opening and therefore the results might conceivably be quite different if some other speed had been employed. Consequently, conclusion 3, i.e., "The Kadenacy effect vanishes if the discharge opening becomes relatively small." One inference that full advantage cannot be taken of the Kadenacy effect because "exhaust ports or valves cannot be opened rapidly enough," cannot be valid except when the exhaust-valve acceleration at the time of opening is low or at best comparable with that which obtained during the authors' experiments. For this reason it would appear that their results cannot properly be used as the basis for any general theory to explain the phenomena and should not be quoted as confirming such a theory based on pure speculation.

The authors assert that the hypothetical assumed average speed of 450 m per sec is derived from some preconceived theory of operation, and quote from various Kadenacy patent specifications in support of this assumption. This does not conform to my understanding of the Kadenacy patents. From a complete study of all of these it is obvious that the structures covered by the patents rest entirely upon experimental data from which empiric relationships are established. Obviously, variable coefficients must be determined in order to take care of such variable conditions as, for example, speed of opening of the exhaust valve.

An experimental engine, built by the company with which the writer is associated, develops mean effective pressures of more than 100 psi without a blower. Analysis of the exhaust gas, as well as direct measurements indicates that the volume of air passing through an engine exceeds the displacement by 60 per cent.

An Analysis of Intercooled Supercharging

By RALPH H. MILLER,[1] MILWAUKEE, WIS.

In this and in an earlier paper,[2] the author analyzes the internal-combustion engine as a heat engine. He finds that with present-day materials, the output of the internal-combustion engine is limited by the temperatures reached in the internal surfaces and not by lack of air to sustain combustion. A method is developed by which the output capacity of four-cycle engines may be increased by more than 100 per cent without exceeding practical and previously established temperatures of internal surfaces.

In a previous paper,[2] the author summed up his analysis of intercooled supercharging in a rating graph which is reproduced in Fig. 1, herewith.

Curve *A* in the graph shows that with standard supercharging without air cooling 133 per cent of the mean indicated pressure (mip) is carried at 4 psi pressure with the same cycle mean temperature. This represents a gain of 36 per cent in brake mean effective pressure (bmep). Since that paper was presented a series of tests has been conducted to check the theories presented therein.

Efforts were made to correlate calculated cycle mean temperatures and the surface temperatures of the internal walls, which are obviously what affect the engine parts and not the temperature of the gases.

An engine operating at 600 rpm, and another engine tested at 327 and 360 rpm were used in these tests. Equipment was installed to measure the heat flow to the cooling-water jackets with great accuracy. Means were also installed for controlling the air-intake temperature to the blower or the engine manifold.

The cooling-water mean temperature was kept at 155 F and the rate of circulation maintained constant for all loads and speeds.

The formula for rate of heat transmission

$$dq = U \times dA\ (t_1 - t_0)$$

where

dq = Btu per unit of time
dA = area
$U \times dA$ = over-all conductance of wall per unit of time
t_1 = temperature of internal hot surface
t_0 = temperature of cooling water

permits us to conclude that the internal-wall temperature t_1 is unchanged when, in any given engine, changes are made in manifold pressure or temperature or combustion efficiency, but the load is adjusted so that dq remains constant.

The rate of heat flow to the cooling water (liners and cylinder heads) is plotted in Fig. 2 for the 600-rpm engine. Curve 1 shows the naturally aspirated engine from 58 to 85 bmep. Curve 2 is the engine supercharged with the Buchi system with two exhaust pipes to the turbine. Curve 3 is the same as curve 2 but with intercooling to 90 deg F in the air-inlet manifold.

The naturally aspirated engine is rated at 80 bmep. The heat flow to the cooling water (dq) is 12,000 Btu per min at this load. When the engine is operated supercharged with the Buchi system, a heat flow of 12,000 Btu is reached at a load of 102 bmep. Curve 1 in Fig. 3 shows a supercharging pressure of 6.7 in. Hg (3.3 psi) at 102 bmep.

The theoretical rating curve, Fig. 1, shows that on the basis of equal cycle mean temperature of the gases, a rating of 131 per cent of the naturally aspirated indicated rating should be carried at 3.3 lb supercharging pressure.

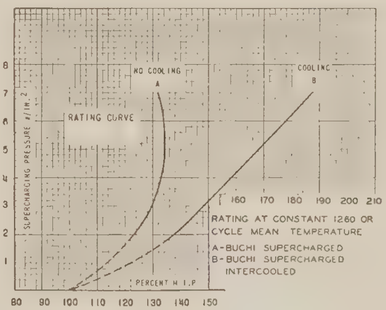

Fig. 1

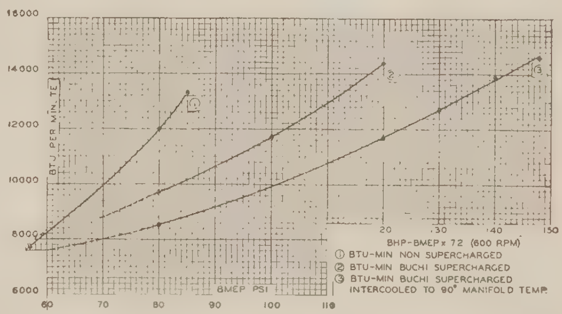

Fig. 2

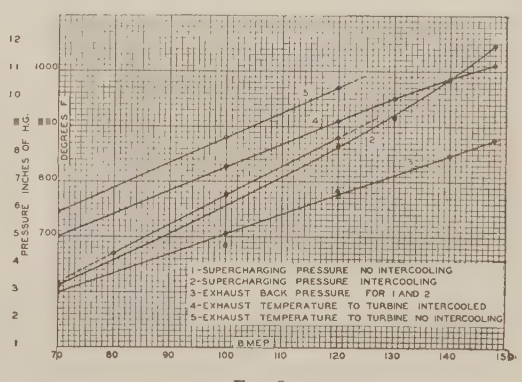

Fig. 3

[1] Chief Engineer, Four Cycle Diesel Division, Nordberg Manufacturing Company. Mem. A.S.M.E.

[2] "Rating Supercharged Engines on the Basis of the Mean Temperature of the Cycle," by Ralph Miller, Trans. A.S.M.E., vol. 65, 1943, pp. 685–696.

Contributed by the Oil and Gas Power Division and presented at the Annual Meeting, New York, N. Y., November 26–29, 1945, of The American Society of Mechanical Engineers.

Assuming a friction mean effective pressure (mep) of 20 psi at 80 bmep and that it increases with the square root of the bmep the mip at 12,000 Btu per min is as follows:

	Mip from Fig. 2	Mip from Fig. 1
Naturally aspirated, $80 + 20 =$	100	100
Buchi supercharged, $102 + \left(20 \times \sqrt{\frac{102}{80}}\right) =$	125	131
Buchi supercharged intercooled, $123 + \left(20 \times \sqrt{\frac{123}{80}}\right) =$	148	158

This shows a difference of $4^1/_2$ per cent in the noncooled and $6^1/_2$ per cent in the intercooled ratings between mip calculated from cycle mean temperatures and actual tests, recording heat flow to cooling water.

This discrepancy is probably caused by increased afterburning and diminishing expansion coefficient with the later cutoff when supercharging. The same cause brings about the nonparallelism of the curves 1 and 2, that is, the combustion efficiency falls off at a faster rate in the nonsupercharged than in the supercharged engine.

In Fig. 4 the rate of heat flow to the cooling water is plotted versus bmep. Curves 1 and 2 show the heat flow nonsupercharged and supercharged at 360 rpm. Curves 3 and 4 are plotted for 327 rpm, nonsupercharged and supercharged.

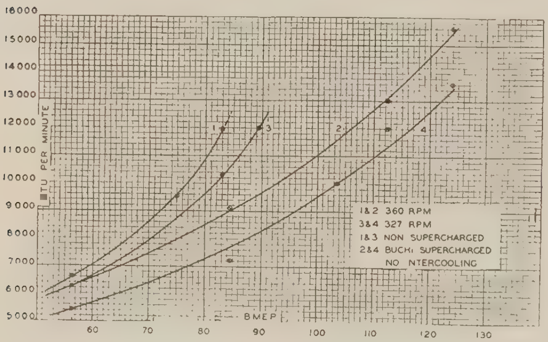

Fig. 4

If a heat-flow rate of 10,000 Btu per min is taken as a maximum for full load the bmep ratings will be as follows:

Engine rpm	327	360
Nonsupercharged oil Diesel, psi	82	77
Buchi supercharged oil Diesel, psi	103	93

The low bmep of this engine when supercharged would seem to be due to insufficient scavenging.

Intercooled Supercharging

At 4 lb supercharging pressure the bmep can be increased between 21 and 26 psi at the same heat flow to the cooling water when the supercharging air in the inlet manifold is cooled to the air temperature at the blower intake.

The graphs in Fig. 5 show manifold temperature versus bmep developed by the high-speed engine at two different rates of heat flow to the cooling water, namely, 10,000 and 12,000 Btu per min. Selecting for an example, the test point at 126 F manifold temperature and 105 bmep with a heat flow of 12,000 Btu per min, a cycle mean temperature of 1262 deg R is calculated as follows:

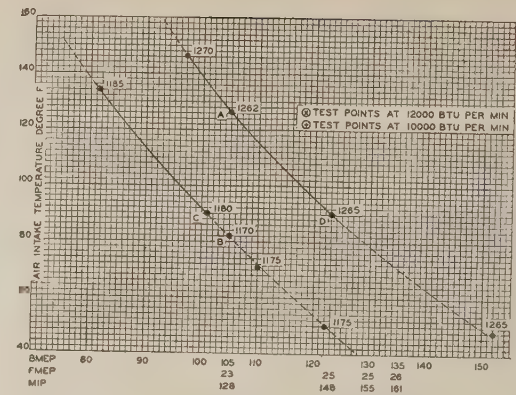

Fig. 5

$$\text{Mip} = 105 + \left(20 + \sqrt{\frac{105}{80}}\right) = 128$$

P_1 = supercharging pressure; nonintercooled line, Fig. 3 = 3.45 psig

Cutoff for 128 mip and 3.45 psi, Fig. 6 = 14.18

Ratio Tm/T_1 for cutoff 14.18, Fig. 7 = 1.92

$T_1 = 126 + 460 + t_{ch}$ = (Equation [9], reference 2) = 657 deg R

$Tm = 1.92 \times 657 = 1262$ deg R

The 10,000-Btu line shows a manifold temperature of 82 deg F at the same load. The initial temperature and the cycle mean temperature at this point are then

$T_1 = 657 - (126 - 82) = 613$ deg R

$Tm = 613 \times 1908 = 1170$ deg R

(The supercharging pressure P_1 has dropped from 3.45 to 3.3, Fig. 3, so that the Tm/T_1 ratio changes from 1.92 to 1.908.)

Reducing the manifold temperature from 126 to 82 deg F has reduced the cycle mean temperature from 1262 to 1170 deg R, and the heat flow to the cooling water from 12,000 to 10,000 Btu per min. We then have

$$\frac{12{,}000}{10{,}000} = \left(\frac{1262}{1170}\right)^n$$

where $n = 2.4$.

In other words, when the manifold temperature is reduced the heat flow to the cooling water, and therefore the internal wall temperature, decreases with the power of 2.4 of the cycle mean temperature.

Now, when the load is increased from C to D at 82 deg F manifold temperature to the point where the heat flow to the cooling water is again 12,000 Btu per min, it is seen that heat flow increases with approximately the same power of the cycle mean temperature, as follows:

At point C on the 10,000-Btu line, we have

$T_1 = 90 + 460 + 71.5 = 621.5$ deg R

P_1 = supercharging pressure (from Fig. 3) = 3.1 psig

Mip = 101 + 22.5 = 123.5 psi

Ratio Tm/T_1 (from Fig. 6) = 1.90

Then

$Tm = 621.5 \times 1.9 = 1180$

Point D on the 12,000-Btu line and 90 deg F air temperature reads 123 bmep; then

Mip = 123 + 25 = 148 psi

P_1 (from Fig. 3) = 4.2 psig

$T_1 = 90 + 460 + 70.5 = 620.5$ deg R
Ratio $Tm/T_1 = 2.04$
$Tm = 620.5 \times 2.04 = 1265$

The cycle mean temperature has increased from 1180 to 1265 deg

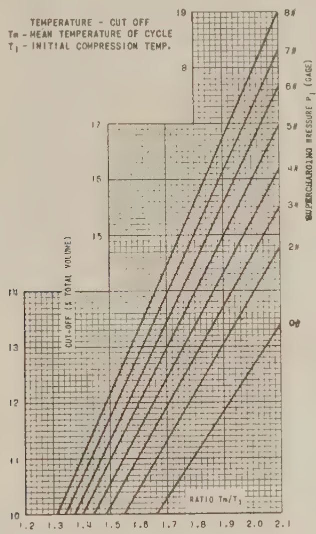

FIG. 6

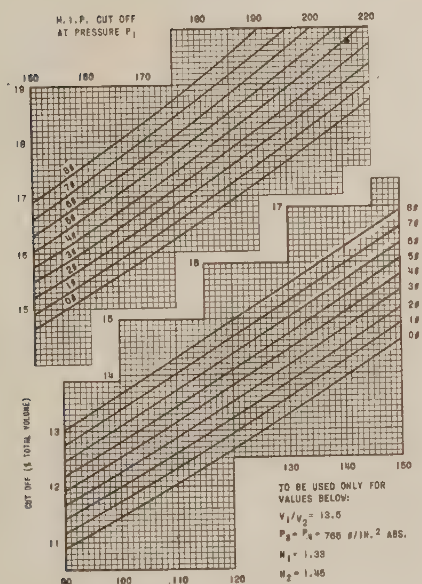

FIG. 7

R, and the heat flow from 10,000 to 12,000 Btu per min, and we have

$$\frac{12{,}000}{10{,}000} = \left(\frac{1265}{1180}\right)^n$$

where $n = 2.6$.

This proves that when the air-intake temperature is changed the load may be adjusted along the line of constant calculated

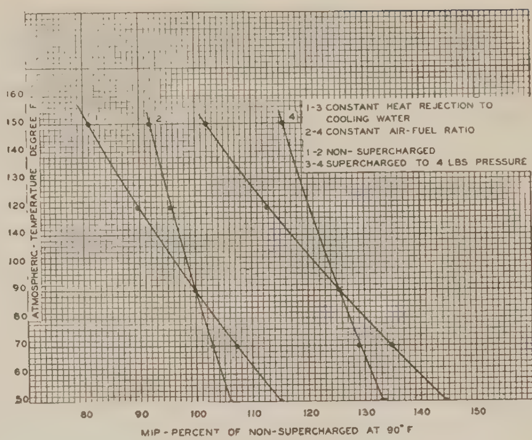

FIG. 8

cycle mean temperature. This loading will maintain the internal temperatures constant as indicated by the rate of heat dissipation to the cooling water.

The constant heat-flow curves in Fig. 5 will show an increase in initial compression pressure with increase in load which is characteristic of turbocharged engines. In Fig. 8 constant cycle temperature lines have been plotted against atmospheric intake temperature and mip for constant manifold pressures; 90 deg F is taken as standard and the point of rating. Curves 1 and 2 are for nonsupercharged and curves 3 and 4 for a supercharged engine. Curves 2 and 4 show the ratings which would be obtained by the conventional method which assumes that the mip is inversely proportional to the absolute temperature, or directly to the air density. This method does not derate sufficiently for temperature increases. Thus if an engine is operating with 115 deg F intake temperature, which is not unusual, it suffers a loss of 8½ per cent in load capacity. Conversely, when the temperature is decreased the load-carrying capacity increases at a rate faster than the air density.

FUEL CONSUMPTION

Table 1 summarizes data from a nonsupercharged, two noncooled, and three intercooled Buchi supercharged tests.

Although the theoretical cycle thermal efficiency is unaffected by the initial compression temperature,[3] these test results show an increase from 34.2 to 35 per cent brake thermal efficiency when cooling the intake air to 90 deg F, at 120 bmep. The fuel consumption is reduced from 0.377 to 0.371 lb per bhp per hr. The heat flow to cooling water drops from 14,500 to 11,700 Btu per min, and the calculated cycle mean temperature from 1365 to 1270 deg R.

When the bmep is increased from 105 to 126 along the 12,300-Btu per min heat-flow line in Fig. 2, the fuel consumption drops to 0.37 lb per bhp per hr, Fig. 9.

The lowest rate of heat flow to the cooling water is 11.15 per cent of the total heat at 147 bmep.

It will be noticed that the excess air is reduced with intercooling. Thus the uncooled engine at 105 bmep shows 27.1, and the cooled engine at 126 bmep 26.4 lb of air per lb of fuel, both at 12,300 Btu heat flow to cooling water.

Where a cooling medium of low temperature is available, such as in cold-storage or ice plants where brine may be used, or in

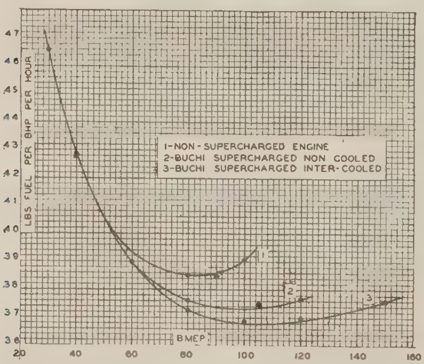

Fig. 9

places where cold well water is available, the air cooling may be carried below 90 deg F to advantage. Fig. 5 shows by extrapolation that with an air-intake temperature of 50 deg F, about 145 bmep is carried with the heat load of 105 bmep on the noncooled Buchi supercharged engine.

In Fig. 10 is plotted the fuel consumption in hhv per hour and per bhp per hour recorded on the intercooled supercharged engine at 327 rpm. The cooling-water heat-flow line for this run is shown on curve 4 in Fig. 4.

The author promoted and directed this development which was started in 1943. The first tests were made in January and February, 1945. The fuel consumption obtained at that time is plotted in curves 3 and 4 in Fig. 10. The engine was operated with air intercooling. At 130 bmep the fuel consumption was 6500 Btu hhv per bhp per hr. This may be the lowest fuel consumption ever recorded on a gas engine.

Without air cooling the consumption will increase about 3 per cent to 6700 Btu. This latter value has recently been confirmed by another enginebuilder who has since taken up the supercharged gas Diesel.

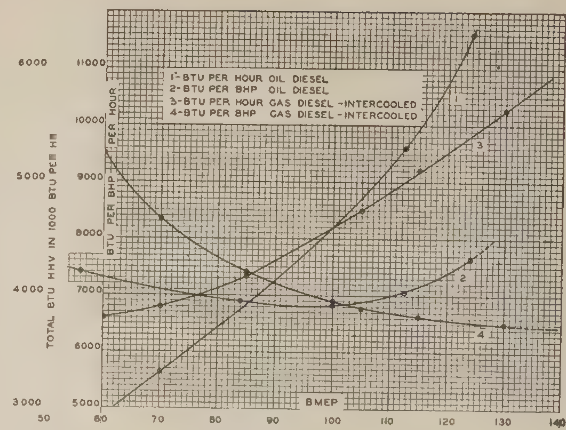

Fig. 10

On the basis of cycle mean temperature, the supercharged gas Diesel will carry a higher mep than the oil Diesel. This is due to better combustion efficiency at high loads.

High-Pressure Supercharging

Points A, B, and C, curves 1 and 2, Fig. 11, are transposed test points on the 12,000-Btu line in Fig. 2. By calculating T_1 for these points, the mean temperature Tm is found, thus permitting other points on the curves to be calculated from Figs. 6 and 7.

If the nonsupercharged engine could be scavenged, the mip would increase from 100 to 109. The curve starting at 109 and 0 supercharging pressure shows the gain obtained by increasing the pressure. The highest load occurs at 5 lb, where the mip is 125. Of this, 9 lb is gained by scavenging and 16 by increasing the supercharging pressure. Above 5 lb gage the load drops off.

By cooling the air in the manifold to 90 deg F or to the intake temperature of the blower, the mip at constant cycle mean temperature will follow curve 2. The 148-mip point is established from the actual heat-flow test curves in Fig. 2. The maximum cylinder pressures are equal at 765 psi for curves 1 and 2 in Fig. 11. The cutoff ratio and compression pressure versus scavenging pressure for rating line 2 is shown on lines 7 and 6. A maximum of 177 mip is reached at 9.5 lb supercharging pressure when the compression pressure equals the maximum cylinder pressure of 765 lb.

Therefore, when maintaining the maximum cylinder pressure of the nonsupercharged engine, the limit of supercharging pres-

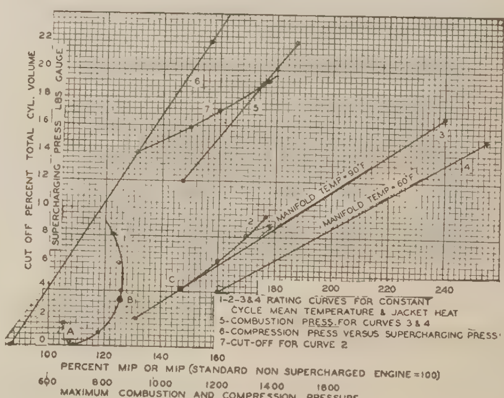

Fig. 11

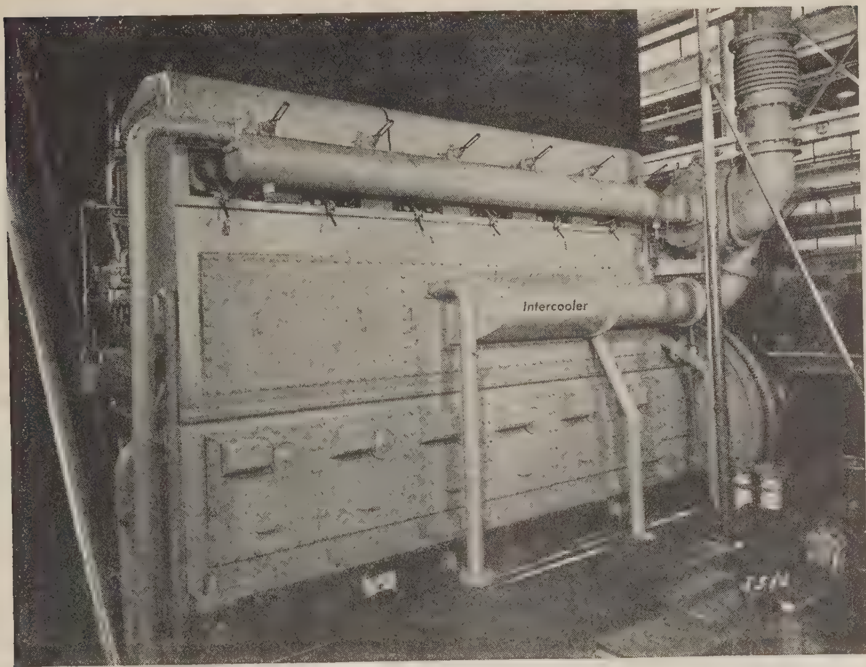

FIG. 12 SUPERCHARGED DIESEL ENGINE WITH INTERCOOLER

sure, with intercooling to blower intake temperature, is reached at about 9.5 lb gage.

Higher supercharging pressures can be used only by permitting the maximum combustion pressure to increase.

The 147-mip point on curve 2 in Fig. 11 has a combustion-to-compression pressure ratio of 1.266. If this ratio is maintained with increasing supercharging pressure and constant air-manifold temperature, we find that with constant cutoff (15.5 per cent) the mip for constant cycle temperature increases directly with the absolute supercharging pressure. The cycle mean temperatures are identical at all loads on curve 3, and the thermal efficiency is constant.[3]

Line 4 in Fig. 11 is plotted for 60 deg F air-intake temperature to indicate the as yet unexplored possibilities of high output of the four-cycle engine. For example, with a supercharging pressure of 22 psig a mip of 318 psi would be carried. The compression pressure would be 1170 psi, and the maximum combustion pressure 1480 psi. The heat flow to the cooling water would be about 5.6 per cent of the total, and the fuel consumption 0.32 lb per bhp per hr; 45.4 per cent of the total heat would go to work and 49 per cent to exhaust and radiation. While these figures will have to be adjusted downward to compensate for increased heat-transfer rate from gas to the walls, due to the increase in gas density, high-pressure supercharging nevertheless holds great promises.

CONCLUSIONS

On the basis of constant internal temperatures, the nonair-cooled Buchi supercharging system permits an increase of 28 to 30 per cent on the brake horsepower of the nonsupercharged engine, or an increase of between 20 and 28 bmep. The cost of equipping an engine with a turbocharger and the Buchi exhaust-pipe system is very nearly in the ratio of this increase so that the final cost per bhp of the supercharged engine is approximately the same as the cost of the standard nonsupercharged engine.

By the simple expedient of adding to the supercharging equipment an air cooler whose dimensions may be 15 in. square × 4 ft long for 2600 cfm, and supplying cooling water at 80 deg F to remove 3 Btu per min per bhp, the engine output is increased to 155 per cent of nonsupercharged rating.

The cost of this cooling equipment will be about $3 to $4 per hp, gained by cooling. The author believes this to be the lowest cost on record for a Diesel-engine horsepower. The extreme simplicity of equipment and ease of operation and maintenance should bring about universal acceptance of intercooling and render the uncooled turbocharged engine obsolete.

Compared with the nonintercooled turbocharged engine, intercooling to 90 deg F reduces the cost per horsepower by about $18^1/_2$ per cent. The weight and volume of the engine are reduced about 20 per cent for the same horsepower.

Beyond this lies high-pressure intercooled supercharging using multiple-stage turbochargers, which promises in the near future to revolutionize the design of internal-combustion engines. Those engineers who accept the challenge of this discovery and bend their efforts toward the solution of the problems involved in developing this new engine will help to guide the internal-combustion-engine industry toward greater expansion and increased importance in our civilization.

Discussion

G. J. HAISLMAIER.[4] The author analyzes the internal-combustion engine primarily as a heat engine. As such it is important that we maintain a balance of heat, adding it where necessary and removing it where it is undesirable. In the case of the supercharger intercooler, that is, the cooling unit itself, we are interested primarily in the removal of heat and generally

[4] Sales Manager, Contract Products Division, Young Radiator Company, Racine, Wis.

speaking, removing as much as possible. In terms of heat transfer we find the engine jacket water at a temperature level too high to afford a means of cooling the supercharged air. We look therefore to an outside source of water, normally the raw-water supply which is used for cooling the engine jacket water and the oil coolers, or in the case of a marine engine, the sea water, in which case we must be careful to design into the intercooler unit a construction with materials that are resistant to salt-water corrosion.

The intercooling of supercharged air is comparatively new; however, we did accomplish this and in production-lot quantities, starting back in 1939, on the smaller high-speed 4-cycle Diesel engines ranging in the neighborhood of 150 to 200 hp. Later on during the war period we did this for other engines also in the higher-speed Diesels, namely, in the 300-hp range. Fig. 13 of this discussion shows a small cooling unit used with a 300-hp marine supercharged Diesel engine. The core element of this unit is approximately 6 in. square and this will give a relative idea of the over-all size of the cooling unit. This unit is capable of handling anywhere from 300 to 600 cfm of supercharged air and of cooling this down to within about 25 deg of the temperature of the sea water. The unit was designed and manufactured entirely of salt-water-corrosion-resistant materials and, in being furnished for the requirements of the United States Navy, was built in compliance with the applicable specifications of Heat Exchanger Specification 66Cl of the Heat Transfer Section of the United States Navy, Bureau of Ships.

Fig. 14 shows the performance curves for this unit, which basic data have served well in approximating the size of the intercooler units being furnished for some of the larger slower-speed Diesel engines today. It will be noted that all of the characteristics are plotted against engine rpm. The sea-water temperature rise is negligible. The sea-water flow rate is such as dictated by the other parts of the cooling system. The air-pressure drop is within an acceptable range, and it will be noted also that the sea-water pressure drop is almost negligible.

In the meantime some of the engine designers had indicated a preference for an intercooler unit which would be round in shape, and from a design standpoint this seems to be the logical arrangement of heat-transfer surface, because of the over-all shape of the unit, the straight-through air flow, and the ease of installation to the engine. Naturally this round-type intercooler would be more desirable, fitting readily and neatly into the air duct from the supercharger blower to the engine intake manifold, and it is generally conceived by the engine designer as a unit which would be about the same diameter size as the air duct, or at least not much larger. An intercooler of this design has been developed, and is shown in Fig. 12 of the paper. This has been applied to one of the larger supercharged Diesel engines. The cooler itself, Fig. 15 of this discussion, is approximately 22 in. diam with approximately 1100 tubes, $^1/_4$ in. diam, making up the tube nest, the salt water from the engine cooling system flowing through the flanges as shown and the air flowing through the tubes. The unit handles approximately 2000 cfm with a pressure drop of about 8 in. water gage, and cools the air to within about 20 deg F of the water temperature.

As yet this type of unit has not been made available in production-lot quantities and there is some doubt that it will be, at least in its present shape and form. It must be remembered that the raw water, or the salt water in marine applications, passes around the smaller tubes in very narrow and restricted passages inside of this round unit. So far the design of this round-type unit has not been cleanable from the sea-water side. However, that factor is being given further consideration and the round-type intercooler may yet be available for the engine designer in the not too distant future.

As in all engineering considerations, design too is a matter of compromise, and in the design of the supercharger-intercooler unit itself the compromise is that of shape and size with performance in terms of cooling efficiency as well as of maintenance and serviceability in operation. There is also a compromise in the arrangement of the heat-transfer surface, that is, a compromise in over-all height and width against pressure drop in the air stream passing through the cooling unit.

The following is what might be considered an over-all compromise in terms of one of the latest intercooling units now being applied to one of the larger slow-speed Diesel engines. This engine, a six-cylinder model, 16-in. bore, 22-in. stroke, operating at 325 rpm when supercharged, has a rating of 1200 hp as against the 750-hp rating unsupercharged. With supercharger intercooling, it is expected to bring the rating of this engine up to 1500 hp at the same engine speed. The intercooler unit has over-

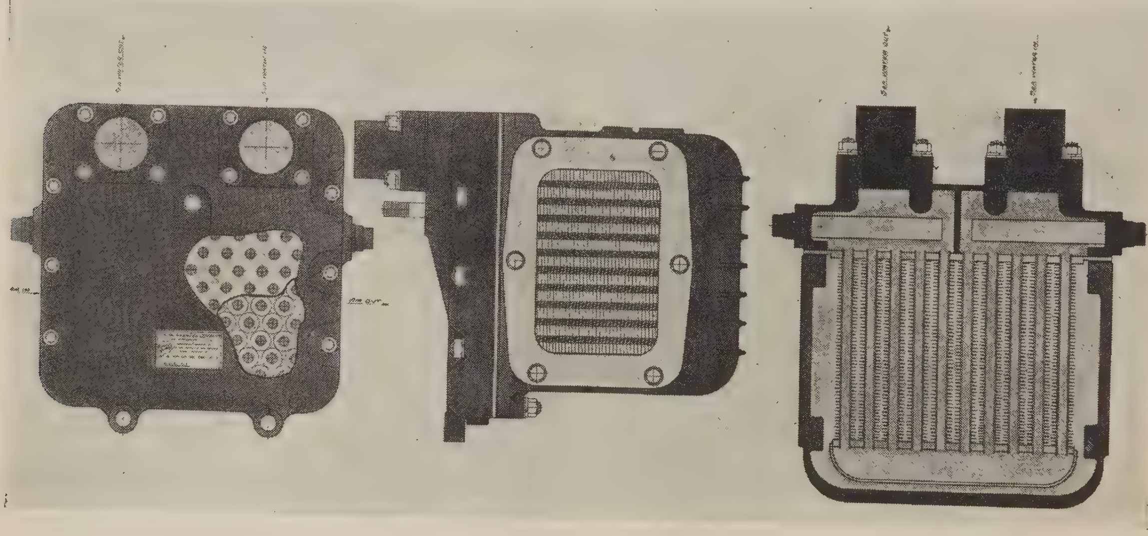

Fig. 13 Details of Supercharger Intercooler Heat Exchanger

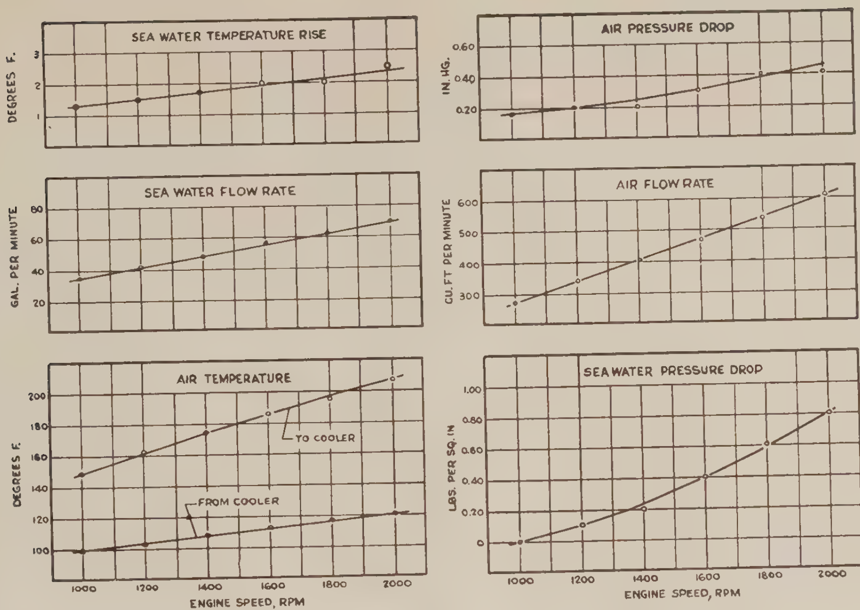

Fig. 14 Performance Curves of Intercooler Heat Exchanger

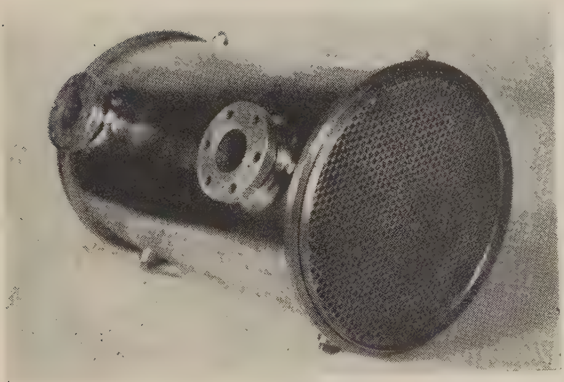

Fig. 15 Round-Type Intercooler Unit

all dimensions of 53 in. length, $18^1/_2$ in. height and depth in the direction of air flow of $7^1/_8$ in., although the core element itself to which the supercharged air stream is exposed, measures only 48 in. between the end headers, $16^1/_8$ in. height and $5^1/_8$ in. depth in the direction of air flow.

This unit in over-all volume is somewhat smaller than the intercooler unit to which the author referred in his paper, and it is offered to give cooling performance even a little better than that same unit. More specifically, it is designed to handle an air flow of 3900 cfm with an air-inlet temperature coming from the supercharger at 155 deg F, cooling the supercharged air down to 90 deg F. The cooling-water temperature maximum is 80 deg F, and with lower water temperatures the leaving temperature of the supercharged air coming off the cooling unit will of course be less, that is, approximately 10 to 15 deg above the water temperature.

In this particular case we have figured on a cooling-water flow of from 200 to 250 gpm, which is the same water flow available for the engine jacket-water heat exchangers and the lube-oil heat exchangers. The raw water would flow through the supercharger intercooler before passing through the other heat exchangers as there is only about a $2^1/_2$ to 3 deg F temperature rise in the cooling water passing through the supercharger intercooler. This unit, incidentally, has approximately 150 tubes, $^3/_8$ in. diam, and in its performance we estimate the pressure drop on the air side will run in the neighborhood of $2^1/_2$ to 3 in. water gage.

The weight of this intercooler unit is approximately 350 lb. As yet it is not being manufactured in production-lot quantities, but even on the smaller-quantity basis the cost figures today indicate that the \$2 per hp figure which the author quotes is not far out of our reach. In fact, depending upon the size of engine and the quantity manufactured at one time, we find current costs on intercooler units of this kind running from \$2.50 to about \$5 per hp, based upon the increase of horsepower which will be obtained from the intercooling alone. This does not take into account the cost of the application and the additional materials such as the duct work and manifolding which the engine manufacturer will have to consider in his design costs. It is a figure based on the cost of the intercooler itself as an accessory item.

This cost, however, will be less as time goes on, particularly as plans are being made eventually to work out a standard intercooler design which can be made adaptable to more than one engine installation and which conceivably may be manufactured in larger quantities, resulting in ultimately lower costs. It is not unreasonable therefore to look forward to approaching the figure of \$2 per hp or possibly even improving upon that figure.

Bavarian Motor Works Altitude-Test Facilities

By E. E. STOECKLY,[1] WEST LYNN, MASS.

Several large-capacity high-altitude low-temperature test chambers for aircraft-engine work were constructed during the war. The present paper describes in some detail the equipment and operation of the first of these at the Bavarian Motor Works.

Early in the year 1941 the German Air Ministry authorized the construction of the first large-capacity high-altitude low-temperature aircraft-engine testing laboratory. This decision was predicated on the conviction that the further rapid development of high engine powers at altitudes could most rapidly be accomplished by ground-level testing under actual high-altitude low-temperature high-speed flight conditions. Of paramount importance was the cooling problem of both air- and liquid-cooled conventional engines, and the satisfactory performance and operation under altitude conditions

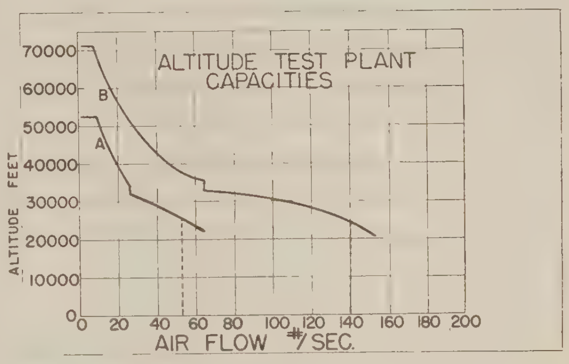

Fig. 1 Test-Plant Capacities

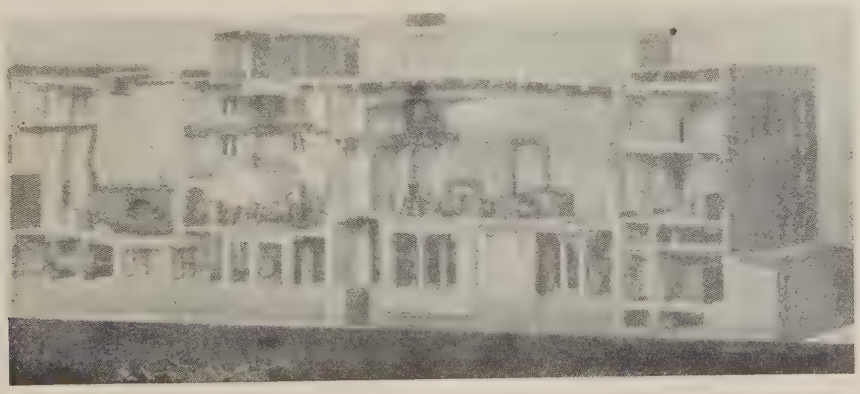

Fig. 2 Cross Section of Test Plant

of their then little-known jet-propulsion engine. Prior to 1941 all laboratory altitude testing consisted of holding only the engine exhaust and carburetor air inlet at altitude conditions. Because of the experience and success that the B.M.W. had with such testing, it was directed to build the first really large altitude-test plant. The plans called for a maximum refrigerated air supply of 53 lb per sec at —80 F, and an evacuation capacity of 53 lb per sec at 26,000 ft altitude, with a maximum operating altitude of 52,500 ft, as given by curve A, Fig. 1.

Shortly after authorizing the first plant, the German Air Ministry, often referred to as R.L.M., authorized the construction of four more such plants, some of which were to be over twice as large as the Bavarian Motor Works (B.M.W.) plant. The new plants were to be for the research establishment of the Luftwaffe, known as E.D.L; German Experimental Establishment for Aviation, know as D.B.L; Daimler Benz and Junkers Motor Works. This policy was to make altitude-testing facilities available to the three leading German reciprocating and gas-turbine aircraft-engine manufacturers, as well as the two leading government research institutions. The two government plants were to have exhausting and refrigerating capacities as shown by curve *B*, Fig. 1. The plants at the three engine manufacturers were to be as given by curve *A*, Fig. 1, with space and foundations provided for eventually increasing the plant capacity to curve *B*, Fig. 1.

Between 1941 and 1943, as the hopes for larger engines rose and fell, doubling the capacity of the B.M.W. plant was authorized and canceled several times. Some 3 years after construction was started, the B.M.W. plant, a cross-section model of which is shown in Fig. 2, went into operation in October, 1944, with a refrigeration and evacuation capacity of 53 lb per sec at 26,000 ft altitude and a maximum working altitude of 52,500 ft. The plant operated successfully from the very beginning and was in continuous service up to the time of occupation by the American forces, except for short outages to repair bomb damage. Be-

cause of the critical shortage of electric power in the Munich area, brought about by heavy Allied air bombardment, the plant could be operated only from late evening until early morning. As the construction of the other test plants was lagging behind, the German Air Ministry made the B.M.W. plant available to the other engine manufacturers on a priority basis.

From October, 1944, to April, 1945, several reciprocating engines and approximately 20 Junkers 004 and B.M.W. 003 jet-propulsion engines were completely altitude-tested.

B.M.W. Plant and Equipment

Test Chamber. The altitude test chamber, as shown in Fig. 3, consists essentially of a large cylinder in which the aircraft engine to be tested is mounted on a movable carriage. Refrigerated air under the desired conditions of temperature, altitude, pressure, and velocity is rammed into the front end of the engine. The exhaust system connected to the rear section of the cylinder removes the exhaust gases and cooling air. In the case of air- or liquid-cooled reciprocating engines and propeller-drive aircraft gas turbines, the power output is transmitted by a drive shaft through the inlet-air elbow to a combination water brake and electric dynamometer located on the left-hand side of the test chamber.

Fig. 4 shows the manner in which a jet-propulsion engine is mounted for testing. The air connection to the front end of the engine is through a free-sliding labyrinth joint transmitting no axial forces. With the unit mounted in a frame on rollers, the thrust output of the engine is transmitted by a system of links and bell cranks to a thrust-measuring scale located in the test chamber and read through a turnable periscope from the operating control room.

Fig. 5 is the schematic piping arrangement of the entire test plant with the principal pressures and temperatures at various points. The left-hand side of the figure shows the refrigerated-air-supply system, and the right-hand side shows the exhausting system. Starting on the left-hand side, normal atmospheric air is compressed to approximately 2.6 atm, cooled by direct-contact water sprays to 60 F, followed by cooling to — 10 F, by an antifreeze solution, and finally cooling to altitude temperature and pressure by expansion through an air-refrigeration turbine. In order to make available a wide latitude of air temperatures and pressures at the test-chamber entrance, the by-pass lines and heat exchanger shown in the line diagram were added. As will

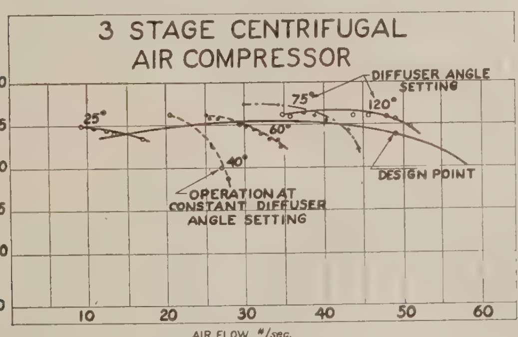

Fig. 6 Characteristics Air-Supply Compressor

be shown later, the purpose of the heat exchanger is to make possible rapid changes in temperature to the altitude test chamber without producing icing conditions.

Air Compressor. The air compressor is a three-stage radial-flow centrifugal unit with automatically controlled variable diffuser vanes and was built by the Brown Boveri Company. Fig. 6 shows a plot of pressure ratios for various air flows for this compressor. The design point and expected curve are given for various constant values of diffuser angle from 25 to 120 deg. These curves show that the compressor can operate stably between air flows of 10 lb per sec to approximately 55 lb per sec. An automatic control, actuated by air flow, varies the diffuser angle setting for operation along the designed curves. Fig. 7 shows the cable and linkage system used to control the angle of the diffuser vanes.

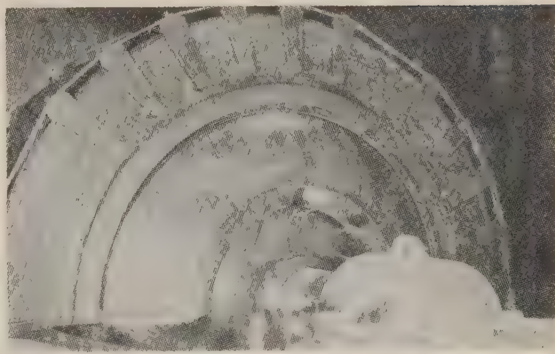

Fig. 7 Variable-Diffuser-Control Air-Supply Compressor

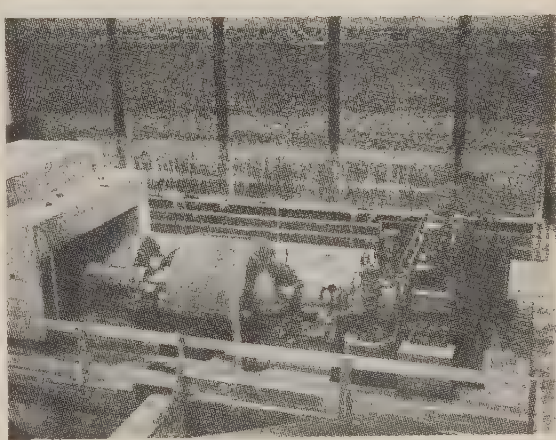

Fig. 8 Air-Supply Compressor and Refrigeration Turbine

Fig. 8 is a view of this compressor with the refrigeration turbine that drives it shown on the right-hand side. The difference in power between the turbine and compressor is made up by the 3300-kw motor on the left-hand side, which is connected to the compressor through a step-up gear.

The compressor driving motor was made large enough to carry full load on the compressor without the help of the refrigeration turbine. Operation of the compressor and refrigeration turbine is at a constant speed of 4370 rpm, while the driving motor runs at 990 rpm. The concrete blocks surrounding the motor were placed there during the last few months of the war as a protection against damage due to Allied bombing attacks. Similar concrete protection was placed around all other vulnerable apparatus as protection against bomb damage.

Air-Cooling System. The air leaving the air-supply compressor is cooled by a heat exchanger from 0 to 70 F, depending upon the method of operation. The next stage of cooling is accomplished

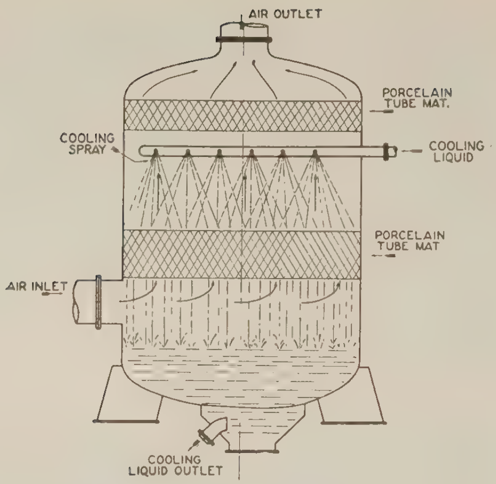

FIG. 9 AIR-COOLING CHAMBER

FIG. 10 SEVEN-STAGE FREON COMPRESSOR

in a water-cooling cylinder, a cross section of which is shown in Fig. 9. The air enters at the bottom left-hand side and passes up through a mat of small porcelain tubes each about $^5/_8$ in. long and $^3/_4$ in. OD $\times$ $^1/_2$ in. ID. These tubes are piled indiscriminately to form a mat with large surface area and many projecting corners. The total depth of this mat is approximately 36 in. Cooling water that is distributed evenly over this mat by means of sprays flows down through and around the tubes, finally collecting in the bottom of the cooler.

After the air has been cooled by contact with the water flowing over the surfaces of the short porcelain tubes, it goes up through another similar mat of tubes approximately 24 in. thick. In going through this second mat the excess moisture carried in suspension is effectively removed by the many sharp corners and narrow twisting paths up through which the air must go. Air leaving the top of this cooling cylinder is approximately at the compressor-discharge pressure of 2.6 atm and saturated with water vapor at a temperature of 60 F. At this temperature and pressure the air will hold in saturation approximately 50 grains of moisture per lb of air. In summer time this may be less moisture than in the incoming air but more than it is likely to hold in the winter months.

The next stage of cooling is similar in construction and operation except that an antifreeze solution is used instead of water. The outgoing air temperature from the second stage of cooling is about 10 F below zero. At this temperature and 2.6 atm, the saturation moisture content is reduced to 1.5 grains per lb of dry air. To accomplish this cooling the antifreeze solution enters the cooling chamber at —16 F and is removed at —6 F. Due to lowering the air temperature, approximately 1320 lb of moisture is condensed out of the air every hour. This is absorbed in the antifreeze solution from which it is removed by special multiple-effect evaporators. This is done on a continuous basis by sending a small fraction of the liquid leaving the air cooler through the concentrating process before going to the antifreeze cooling system. The antifreeze solution used was obtained under the trade name of Reinhartin and is believed to be of a calcium-chloride base with an inhibitor to reduce corrosion.

Cooling Antifreeze Solution. Cooling of the antifreeze solution is accomplished by an integrally designed refrigeration unit manufactured by Brown Boveri Company and sold under the trade name of "Frigibloc." This unit, consisting of a seven-stage centrifugal freon compressor, shown in Fig. 10, is built integrally with a condenser, evaporator, and all necessary accessories. Ther efrigerant gas used is freon F-11. It is extracted at the end of five stages and after passing through an intercooler is returned to the entrance of the sixth stage. Elaborate oil shaft seals are used to prevent air leakage in and freon leakage out. The compressor is driven by a 400-kw direct-connected motor running at 2950 rpm.

Fig. 11 shows the schematic arrangement of the component parts. The centrifugal compressor is shown at the center top and the evaporator, consisting of a tube heat exchanger with the antifreeze solution circulating inside the tubes, is shown directly below the compressor. The intercooler between the fifth and sixth stages is shown on the left-hand side, while the condenser with its liquid aftercooler is shown on the right-hand side. The schematic system for the shaft seal is shown in the upper left-hand corner, while the purging system is shown in the lower left-hand corner.

Refrigeration Turbine. The —10 F air coming from the antifreeze cooling chamber is expanded to altitude pressure in a refrigeration turbine designed and built by Brown Boveri Company. It is of conventional design having a single stage and eight equal admission-valve arcs. Good mixing between the air being by-passed around the turbine and that going through was obtained by building the by-pass directly into the turbine. The turbine buckets and wheel were made of a special nickel steel to withstand the low temperatures encountered. No insulation was applied to the outside of the turbine as it was felt it would interfere with accessibility and maintenance. This results in some heat absorption by the cold air but does not appear to be serious. The turbine is operated at a constant speed of 4370 rpm and is directly connected to the air-supply compressor as a means of loading. Fig. 12 gives the minimum air temperature that can be obtained at the test chamber after correcting for turbine and pipe-line heat loss. As can be seen from the curve, a minimum test-chamber air-inlet temperature of approximately 50 deg F below standard N.A.C.A. altitude temperatures can be maintained with flows of 20 lb per sec and more up to 40,000 ft altitude.

DANGER OF ICING

In the operation of a turbine-expansion cycle of this type for air-cooling there is always the danger of icing resulting from moisture condensation. As air is expanded to lower pressures, at constant temperature, it will hold greater amounts of moisture in saturation. As the temperature is reduced at constant pressure, the amount of moisture that can be held in saturation is rapidly reduced. Fig. 13 shows the plot of constant-saturation-moisture-content lines on a pressure-temperature field. From these curves it can be seen that with a turbine-inlet moisture content of 1.5 grains per lb of dry air, the moisture content can be kept below saturation along the N.A.C.A. altitude-temperature curve only up to 30,000 ft altitude and again above approximately 65,000 ft altitude. Between these two altitudes at N.A.C.A. temperatures and through broader limits at lower

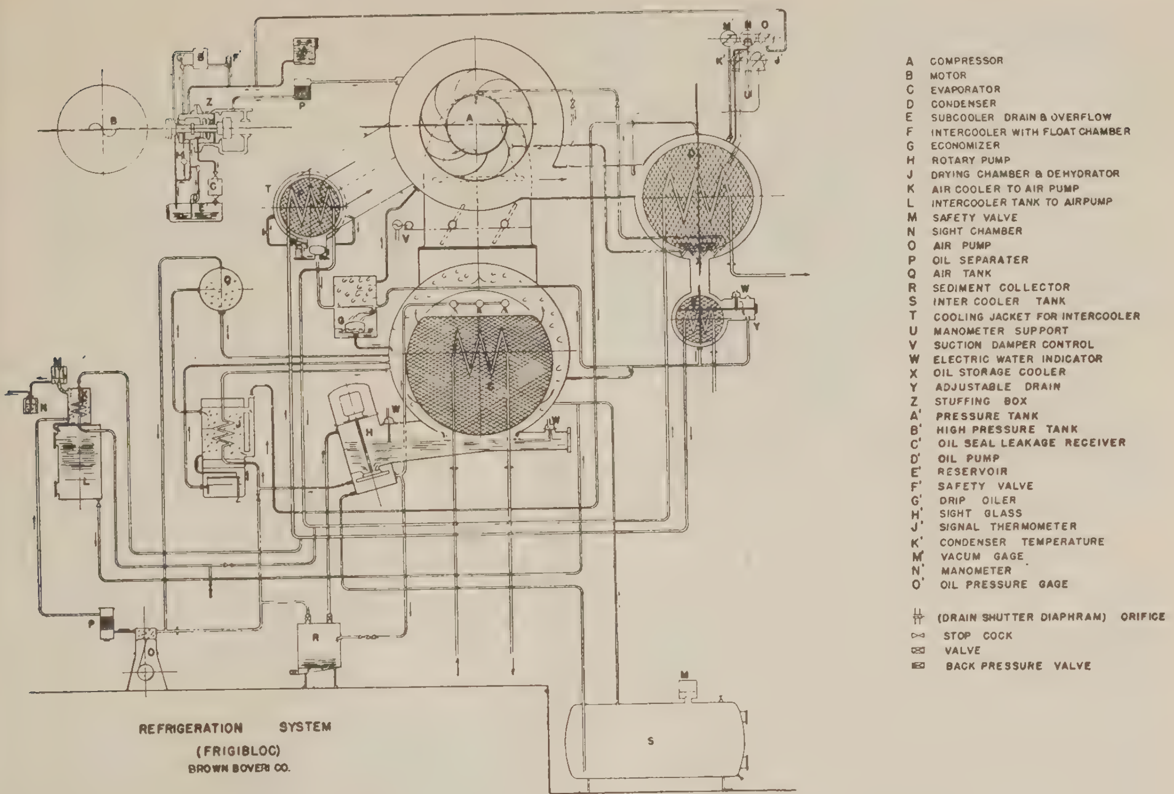

Fig. 11 Schematic Arrangement of Frigibloc Refrigeration Unit

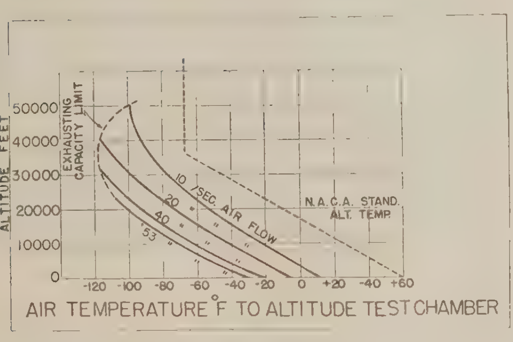

Fig. 12 Minimum Air Temperature to Altitude Chamber

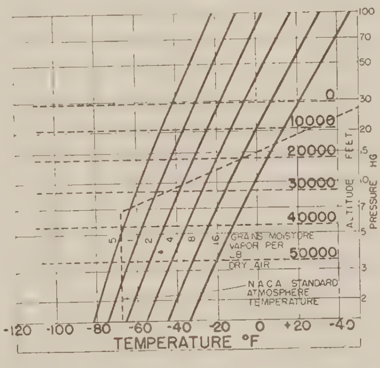

Fig. 13 Saturation Moisture Content at Various Temperatures and Altitudes

than N.A.C.A. temperatures, the air has more moisture than it can hold in saturation and the possibility of ice formation exists.

The designers of the B.M.W. test plant were aware that such icing might give trouble and considered in the initial design stages the installation of chemical driers for removing additional moisture from the air. Because of the size and expense of such driers, they decided to try the system without and find out by experience just how serious the icing problem would be. To date they have operated the plant several hundred hours, although not more than 6 hours continuously, in the range in which icing troubles should occur, as indicated in Fig. 13, and report that they have had no sign of trouble.

The author's personal experience with similar altitude-refrigeration equipment in the United States has shown that icing problems increase rapidly as the air-moisture content gets above 3 to 4 grains per lb and decreases rapidly below 3 grains. This evidence indicates that quite likely little icing trouble will be encountered if the moisture content can be held down to 1.5 grains.

If air temperatures higher than those obtained going through the refrigeration turbine are desired, air can be by-passed around the turbine and the air temperature to the test chamber raised to —10 F, with a moisture content of not over 1.5 grains. If still warmer air is desired, the piping is so arranged that the —10 F air from the antifreeze cooling chamber can be returned to

a heat exchanger between the supply air compressor discharge and the first water air cooler. The maximum temperature that can be obtained in this manner is 120 F. By this method air dried to 1.5 grains can be delivered to the test chamber at temperatures ranging from +120 F to —100 F. This is of particular value when obtaining compressor efficiencies by the temperature-rise method, especially with low inlet-air temperatures.

The heat exchanger between the compressor and the water cooler is used to rapidly heat the cold-air lines between the turbine discharge and the test chamber when shifting from a low temperature point to a higher temperature point. The by-pass valve from the air-compressor discharge to the turbine inlet is rarely used because of the moisture and icing problems encountered by moisture-laden warm air striking cold surfaces.

The inlet-air temperature to the altitude cylinder is controlled by changing the ratio of the air by-passed around the refrigeration turbine to the air that goes through the turbine, with the controls set so as to hold a constant total air flow. The inlet-ram conditions to the engine under test is obtained by varying the total air flow to the test chamber by increasing or decreasing both the air by-passed around the turbine and that going through the turbine. The controls are such as to maintain a constant ratio between the two.

Air-Exhaust System

The altitude cell is exhausted by means of two four-stage motor-driven centrifugal exhausters For low altitudes the exhausting units are operated in parallel while for higher altitudes the exhausters are operated in series. The change-over point is the break noted in curve A, Fig. 1. The larger of the two exhausters, shown in Fig. 14, operates at 3200 rpm and is driven by a 4500-kw 990-rpm motor through a step-up gear. The smaller unit operates at 4785 rpm and is driven by a 2700-kw 990-rpm motor through a step-up gear. These exhausters were built as multiple-stage centrifugal units rather than axial flow because of the belief they would have broader stability limits and would be less subject to performance deterioration due to accumulation of dirt.

Fig. 15 gives the pressure-ratio air-flow characteristics of the two exhausters. Fig. 16 is an outside view of the V1104 or smaller of the two exhausters. The two projecting flanges on the top half-casing hold membrane-type explosion vents that blow out in case of an explosion in the exhaust system. The motors driving these exhausters and the air-supply compressors are of the three-phase alternating-current asynchronous type with wound rotors. Starting is accomplished by inserting liquid resistors between the slip-ring connections. As the speed increases the liquid resistance is decreased until it becomes zero for normal operation. It was originally planned to control the exhaust pressure by speed control obtained by varying the rotor resistance. This did not prove to be practical and as a result the exhausters are operated at full speed, and chamber altitude pressure is maintained regardless of flow, within the limits of operation, by an automatic hydraulic system controlling the throttling valve just ahead of the first exhauster. When the system air flow gets below the stable range of the exhauster, air is bled in from atmosphere to the exhauster inlet.

The exhaust system is so valved that the change-over from series to parallel operation can be made by remote control while the units are operating and the test is going on. Smooth change-over is obtained on the three valves that it is necessary to change by making two self-acting, nonreturn check valves, and the third, a motor-operated gate valve. In changing over it is necessary to change only the motor-operated gate valve and the other two valves automatically follow in the proper sequence.

The hot exhaust gases leaving the test-chamber discharge are reduced to approximately 525 F by automatically operated water sprays. Additional cooling of the exhaust gases to approximately 100 F is accomplished by a surface gas cooler using water as a cooling medium. When the exhausters operate in parallel each discharges to the atmosphere through a brick stack. When the two operate in series an additional surface gas cooler is placed between the two exhausters to reduce the inlet temperature of the second one to approximately 100 F.

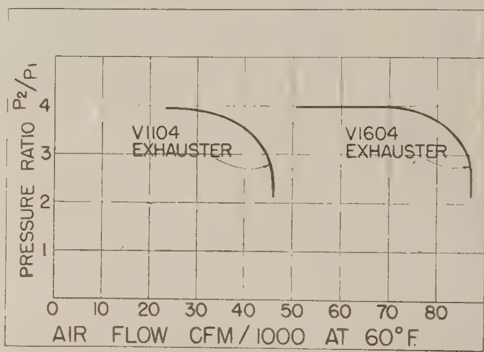

Fig. 15 Characteristics of Exhausters

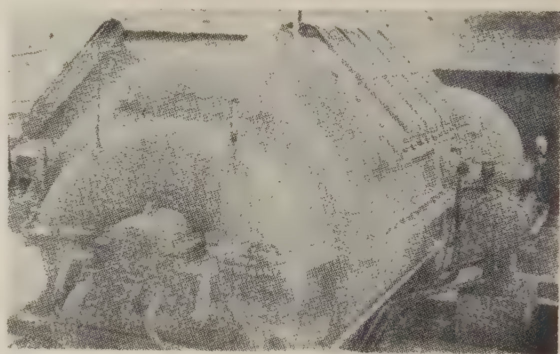

Fig. 16 Four-Stage Centrifugal Exhauster

Altitude Test Chamber

The altitude test chamber is a cylindrical body about 26 ft long and 12.5 ft diam. To withstand possible explosions, the chamber was tested with an internal pressure of 150 psi. The side walls are 0.8 in. thick and the end domes 1.38 in. thick. Since they had had no previous experience with such chambers, four large membrane explosion reliefs $34^1/_2$ in. diam were pro-

vided on the top side of the chamber. In order that the escaping gases from these vents would not damage the building, an explosion shaft was built above the chamber. To date no explosions have been experienced. This has been attributed to the large amount of excess air. Starting of the engine has always been on gasoline and some fires on starting have occurred. These have always been quickly extinguished by closing off the cooling-air supply to the chamber and injecting CO^2 gas. Experimental attempts were made to extinguish fires by quickly raising the altitude to 50,000 ft. This procedure failed to put out the gasoline fires. The author has seen similar oil fires in altitude chambers that were quickly put out by raising the altitude to 40,000 ft.

The entire exhaust-pipe system is protected against explosions and overpressure by a large number of explosion valves built especially for this particular job. These valves are spring-closing check valves of very light construction so that any sudden rise in pressure will quickly open them.

Access to the altitude chamber is obtained by removing the entire end dome and exhaust elbow. This operation is made entirely automatic, requiring only the pressing of several buttons, by the ingenious use of two power-operated bayonet-ring joints. Fig. 17, which is an end view of the altitude chamber, shows the large ring bayonet joint. After the two joints are opened a jib crane supporting the discharge elbow and end dome swings the assembly out of the way. In the center can be seen the exhaust nozzle of the jet engine under test together with the supporting test frame on which it is mounted.

All electrical, pressure, temperature, and fuel-supply lines to the test frame are made by quick connectors. This allows the

Fig. 17 Altitude Test Chamber

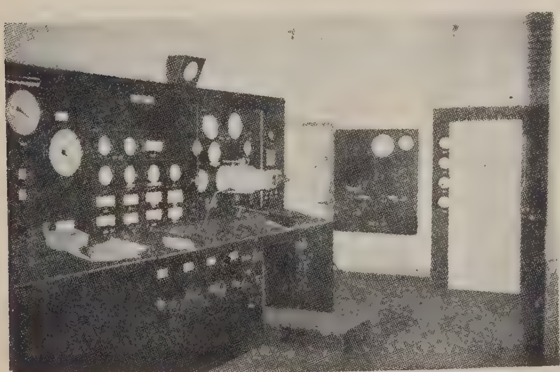

Fig. 18 Engine-Control Board, Altitude Test Chamber

Fig. 19 Refrigeration and Evacuation Control Room

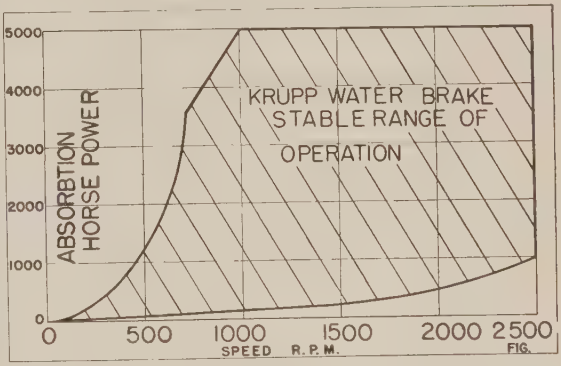

Fig. 20 Characteristics of Froude Water Brake

entire engine assembly to be quickly removed or installed. Such a complete change has been made in less than 2 hr. Fig. 18 is a view of the instrument board in the engine control room. In the center can be seen the turnable periscope used for viewing the engine in the protected altitude chamber. Important temperatures and pressures needed for the proper operation of the engine are given by direct-reading instruments directly in front of the operator. Special test temperatures are read on portable-type potentiometers on the left-hand side of the control board, while special pressures are read on mercury manometers on the right-hand side.

Fuel flow metering equipment is placed in a large tank that is vented to the altitude chamber. Two systems were originally set up to serve as a cross-check. One was a weight-tank system and the other was a volume measurement in which photoelectric cells operated an electric timer. Owing to trouble the photoelectric-cell volume method was discarded and the weigh-tank readings taken without a check method.

Speed measurements were made using a standard aircraft-type tachometer. On jet-propulsion engines, engine speed was held constant and of an exact value by making a matching stroboscopic disk appear stationary. The disk was driven by a small synchronous motor connected to a small synchronous generator on the engine. The flashing light source for the stroboscopic disk was from a special constant-frequency source and did not depend upon power-line frequency.

Fig. 19 is a view of the refrigeration and evacuation control room. From this point the operator controls the altitude pressure in the test chamber, the inlet-air temperature, and the inlet-air velocity or ram pressure. This information is trans-

mitted to the operator from the operator in the engine-control room over a public-address system.

Testing Propeller-Drive Engines

Propeller-drive engines were loaded onto a combination water brake and electric dynamometer. The water brake, whose characteristics are given in Fig. 20, was of the Froude design and had a capacity of 5000 hp over a speed range of 1000 to 2500 rpm. This brake was cradled with and directly connected to a Siemens Schuckert electric dynamometer that was capable of absorbing 1100 kw as a generator and developing 780 kw as a driving motor. The electric load of the dynamometer was loaded into a d-c — a-c motor-generator set that pumped back into the main a-c power lines. The total torque developed by the water brake and electric dynamometer was read on a single electric light beam weigh scale.

In spite of being designed and built under wartime conditions, no effort or expense was spared to make this plant the very best in all respects. That the Germans succeeded in this is testified to in the excellent manner in which the plant operated.

Peanut-Meal Plywood Glue

By R. S. BURNETT[1] and E. D. PARKER[1]

In this paper the results are given of work done at the Southern Regional Research Laboratory in which specifications were established for peanut meal for use in preparing plywood glue. A satisfactory formula has been developed. Joint tests show that the peanut-meal glue meets the requirements established for casein and casein-type glues. Comparisons of peanut-meal glues with other water-resistant glues are made.

THE FIRST large-scale application of an oilseed meal to the preparation of plywood glues began in 1927 with the use of soybean meal from Manchuria. This development took place in the Pacific Northwest to meet the needs of the Douglas-fir plywood industry for a cheap water-resistant glue. Although soybean-meal glue is more suitable for softwoods than for hardwoods, considerable amounts are used on hardwoods grown in the eastern and southern United States, especially in the manufacture of water-resistant box shooks (1).[2] While the preparation of plywood glue from other oilseed meals such as peanut (2, 3) cottonseed (4), castor-bean (5), and hempseed (6) meals has been investigated, to our knowledge only soybean-meal plywood glue has been used in significant amounts in this country. Of the latter 30,000 tons were consumed in 1942 (7). The present investigation is concerned with the preparation of a plywood glue from peanut meal.

The increase in peanut acreage in the South during the past ten years has made available a supply of protein-rich meal, but the preparation of plywood glue from this meal has been prevented by lack of the necessary technical information. The required information must include the development of a formula for preparing a suitable glue which must not only be capable of making a strong glued joint but must have flow properties that permit the glue mixture to fit effectively into the mechanical processes used to make plywood. Spreading characteristics, "working life," assembly time, etc., are all dependent on good flow properties. It is necessary to know also what influence the processing conditions employed to separate the seed into oil and meal have on the suitability of the meal for use in plywood glue.

As a result of work completed to date at the Southern Laboratory, specifications have been established for a peanut meal suitable for use in preparing plywood glue; a satisfactory glue formula has been developed; and information has been obtained with respect to the behavior of the glue under varying conditions of assembly time, pressure, etc. Comparisons of peanut-meal glues with other water-resistant glues have also been made.

Test Methods

The only way to evaluate a plywood glue is by gluing wood and measuring the strength of the joint obtained. Methods for evaluating plywood glues by the plywood and the block shear tests, developed by the U. S. Forest Products Laboratory, have served as a basis for Federal specifications for water-resistant glues (8, 9). The use and interpretation of data obtained by the application of these methods are discussed in several readily available publications (10, 11, 12). Such methods are subject to many variations which are difficult to control; they are not sufficiently accurate to measure small differences but they provide a means of making relative comparisons of one product with another. What actually is measured by such methods is the strength of the glued joint obtained rather than the strength of the glue. In other words, these methods of evaluation serve as a measure of the success of a gluing operation with a given glue.

The three principal tests required to evaluate a plywood glue are the dry and wet plywood shear test, the block shear test, and the measurement of the viscosity of the glue to determine its working life and setting properties.

The plywood shear test is made on specimens of birch plywood which have been prepared with the glue to be evaluated. The test pieces are subjected to tension in a standard plywood shear-testing machine until the joint fails. The load required to break the test pieces and the amount of wood failure is measured on dry joints and on those which have been soaked in water for 48 hours. This test is especially valuable for measuring the resistance of a glued joint to water. The specifications for casein and casein-type water-resistant glues (8, 9) require dry and wet plywood shear strengths of 340 and 140 pounds per square inch, respectively. There was no wood failure found in any of the wet joints tested except those made with one of the two lots of the casein glue mix containing blood and soybean meal reported in Table 9. In the plywood shear test the grain of the core of the 3-ply test pieces is at right angles to the faces.

In the block shear test the minimum requirement is 2800 lb per sq in. (8, 9). The grain of the two glued hard-maple blocks is parallel and a compression force is applied in the direction of the grain.

According to Federal specifications, "a glue shall be considered to have reached the end of its working life when it reaches a viscosity of 800 poises." For this test an orifice-type viscosimeter is recommended. However, for simplicity and speed of operation, the present investigators prefer to use a MacMichael rotating-cup viscosimeter employing a bob suspended from a torsion wire. When wire No. 26 is used with this instrument a reading of 290 deg is roughly equivalent to the maximum viscosity of 800 poises specified. Since the peanut-meal glues exhibit thixotropy, they must be stirred thoroughly to break down incipient gel formation before reliable viscosity readings can be made.

The gluing schedule followed in all of the plywood shear tests reported herein, unless otherwise indicated, was as follows:

Glue to water, proportion by weight	1 to 3
Temperature of wood and glue	75 to 77 F.
Glue spread	70–75 lb per 1000 sq ft
Closed assembly time	5 to 9 min
Pressure	150 lb per sq in. overnight at 75 to 77 F.
Age of glue mixture when used	1 hr
Moisture content of wood and of test pieces	6 to 7 per cent
Number of tests for each average value reported	15 (3 panels)

[1] Southern Regional Research Laboratory, New Orleans, Louisiana. One of the laboratories of the Bureau of Agricultural and Industrial Chemistry, Agricultural Research Administration, U. S. Department of Agriculture.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Wood Industries Division.

For the block shear test the gluing schedule was the same as for the plywood shear test with the following exceptions:

Pressure, 200 lb per sq in.
Number of tests for each average value reported, 5–15.

To control the moisture content in the wood and test samples used for the plywood and block shear tests an inexpensive, easily constructed, constant humidity room was built. This was described in a previous publication (13). Test samples held in this room for 72 hours at a relative humidity of 32 per cent reach an equilibrium moisture content of 6 to 7 per cent.

Formula Development

Finely ground oilseed meals are required for the preparation of plywood glues. Because of the 6 to 10 per cent of oil which remains in hydraulic-press meals a flour cannot be prepared by ordinary sifting methods. It is necessary therefore to employ an air separator to obtain a flour of the desired fineness. The peanut flours used in this investigation were ground and sized so that 80 to 90 per cent would pass through a 200-mesh sieve; the sieve tests being run after the oil was removed by means of solvent. The oil remaining in the meal serves to prevent the glue from foaming during the mixing and spreading operations.

A readily available peanut-meal flour, Table 4, meal No. 1, which had been produced under controlled conditions for use as a food was chosen for the preliminary work on the development of a plywood-glue formula. It had a high protein content and was processed to separate the oil and meal at relatively low temperatures. Subsequent work showed this to be a good choice and this flour, or one prepared under similar conditions, was used in the work reported here, unless otherwise indicated.

Casein and soybean-meal glues are usually made up with water and various combinations and amounts of sodium hydroxide, lime, and sodium silicate. As would be expected, preliminary experiments indicated that peanut meal so combined behaved in a manner generally similar to that of soybean meal and casein.

A joint which has a high dry strength can be prepared with peanut meal by the use of sodium hydroxide and water alone. The addition of lime to such a mixture provides an irreversible gel which is necessary for wet strength in the glue bond. The addition of sodium silicate in amounts up to 15 parts per 100 parts of meal greatly improves the spreading qualities of the glue. Best results are therefore obtained when all three alkalies are present in the glue mixture.

Taking into account viscosity characteristics, working life, water requirements, and the wet and dry strengths of the plywood joint obtained, the combination of alkalies which has given the best results with peanut meal is: hydrated lime 15 parts, sodium hydroxide 4 parts, and sodium silicate 15 parts per 100 parts of peanut meal. Some of the data obtained in arriving at this formula are given in Table 1. In the series of tests recorded in the table the amount of sodium silicate and tetrasulphide, discussed later, was held constant. The addition of hydrated lime up to 15 parts per 100 parts of meal was found to increase the wet shear value. The use of less than 10 parts of hydrated lime gave glue mixtures with unstable viscosities, whereas with the addition of 10 and 15 parts of hydrated lime the viscosities were stable at all concentrations of sodium hydroxide shown. Increasing the amount of sodium hydroxide from 2 to 6 parts increased the dry strength somewhat and lowered the wet strength. A good compromise therefore is the formula containing 15 parts of hydrated lime and 4 parts of sodium hydroxide per 100 parts of meal. However, any one of the last six formulas in Table 1 provides good joints and has good viscosity characteristics.

A plywood glue which will produce a joint having a wet strength up to about 80 lb per sq in. can be prepared by the addition of lime, sodium hydroxide, and sodium silicate to the peanut meal. However, to further increase the water resistance of the glue it is necessary to use, in addition to lime, another insolubilizing agent, and the most satisfactory one which has been tried is carbon disulphide (14, 15). Carbon disulphide is recommended for use in soybean glue. It is sold mixed with equal parts of carbon tetrachloride to eliminate hazard of fire and the mixture is called "tetrasulphide." The influence on the plywood shear test of carbon disulphide, in the form of tetrasulphide, is shown in Table 2.

TABLE 1 EFFECT OF SODIUM HYDROXIDE AND LIME ON THE VISCOSITY AND PLYWOOD SHEAR STRENGTH OF PEANUT-MEAL GLUE WITH A 1:3 RATIO OF MEAL TO WATER[a]

Hydrated lime, per 100 g of meal, g	Sodium hydroxide per 100 g of meal, g	Viscosity in MacMichael deg wire No. 26				Plywood shear tests

15	4	56	67	74	76	424–26	139
15	6	81	80	79	63	400–26	121

[a] The amounts of sodium silicate and tetrasulphide were held constant at 15 g and 2 ml, respectively, per 100 grams of meal.
[b] Ratio of meal to water increased to 1:3.25.

TABLE 2 INFLUENCE OF THE CARBON DISULPHIDE IN TETRASULPHIDE[a] ON THE VISCOSITY AND WATER RESISTANCE OF PEANUT-MEAL GLUE

Tetrasulphide per 100 g of meal, ml	Viscosity in MacMichael deg, wire No. 26				Plywood shear tests	
	1/2 hr	1 hr	2 hr	4 hr	Dry strength lb per sq in.; Wood failure, %	Wet strength lb per sq in.
0	53	45	45	37	432–18	48
1	52	54	57	56	433–13	118
2	51	69	71	73	444–15	140
3	61	97	94	97	412–19	150

[a] Equal parts of carbon disulphide and carbon tetrachloride.

From the standpoint of cost, viscosity stability, and water-resistance the use of 3 parts by weight of tetrasulphide per 100 parts of meal (2 ml per 100 gm) is satisfactory.

The complete formula for peanut-meal glue as compared with two commercial soybean-glue formulas is given in Table 3. This peanut-meal glue formula was used in all the work reported in this article, unless otherwise indicated.

The low water requirement of the peanut-meal glue is important because it permits the addition of less water to the veneer in the gluing operation, with the result that less water need be removed from the plywood in the drying tunnels than is necessary with glues which contain larger amounts of water.

[a] Two lb water added to 50 lb peanut flakes before cooking.
[b] Ten parts peanut oil added to 90 parts solvent-extracted meal in order to prevent the glue from foaming in the spreader.

Choice of Meal

As pointed out, the processing conditions employed to prepare peanut meal have considerable influence on the suitability of the meal for use as a plywood glue. This is shown by the data presented in Table 4.

The solubility of the protein in peanut meal varies with variations in the processing conditions employed to cook and press the rolled meats. This variation referred to as degree of denaturization, can be estimated from the percentage of the total meal nitrogen which is soluble in 1 molar sodium-chloride solution (16). Most commercial hydraulic-press peanut meals appear by this test to be appreciably denatured (low nitrogen solubility) as indicated in Table 4 and in an earlier publication (17). If the meals in Table 4 are divided into those which have a nitrogen solubility in 1M sodium chloride of 69 per cent or better (group I) and those which have a lower solubility (group II) it can be seen that the meals in group I make more satisfactory glues than those in group II. In most cases both dry and wet plywood strengths as well as the block shear strength is low when glues prepared from meals in the low-nitrogen-solubility group are used, the low wet strength being especially marked. The lower test values in group II are probably due, in part, to the necessity for using more water in preparing the glue mixture when the protein in the meal has been appreciably denatured. It is also possible that denaturization inactivates some of the groups in the protein molecule which are capable of reacting with lime and carbon disulphide to increase water resistance.

An examination of the conditions of time and temperature used to prepare commercial meals 1 and 6 (group I) shows that maximum cooking temperatures of 210 to 215 F for 76 to 80 minutes provide conditions for satisfactory oil recovery and at the same time produce a meal which is suitable for use as a plywood glue.

Nevertheless, application of these conditions may not produce a satisfactory meal in all oil mills, and specific directions for preparing meal cannot be given. Each mill will need to determine the best procedure for preparing a meal in which 70 to 80 per cent of the total nitrogen is soluble in 1M sodium chloride. As a further check a plywood-glue test should be made with meals which meet the solubility specification. The complete specifications for meal which has uniformly given good results when used as a plywood glue follow:

Protein (N × 6.25)	50 per cent minimum
Percentage of total meal N soluble in 1M sodium chloride	70 per cent minimum
Sieve test	80 per cent or more through 200 mesh
Oil	6 per cent minimum

The meals listed in Table 4, Nos. 11–17, were prepared in a pilot-plant special-model hydraulic press. Our experience and that of others have shown that meals prepared in a small mill may differ considerably from meals prepared under the same cooking and pressing conditions in a mill of greater capacity. Although a satisfactory meal can be prepared in the pilot plant by heating rolled meats to temperatures as high as 240 F for 60 min (meals Nos. 12 and 15) it would be unsafe to conclude that these conditions would yield the same results in a larger mill.

It is probable that the amount of water present or added to the flaked peanuts and the rate at which the water is driven from the flakes during the cooking operation accounts for the difference in the degree of denaturization of the meal obtained in various mills even though the cooking time and temperature remain the same. Fontaine, Samuels, and Irving (16) have shown the influence of water vapor on the degree of denaturization of the protein in cooked peanuts.

Peanut shells are incompletely removed prior to processing or

are later added to peanut meal which is intended for use as feed, the minimum protein (N × 6.25) requirement being 48 per cent. The presence of shells in meal intended for use as plywood glue, however, acts as a filler and should be avoided. The soybean-plywood-glue manufacturer pays a premium in order to obtain a meal which has a high protein content. The peanut-meal manufacturer should have no difficulty in preparing a meal containing 50 per cent or more protein (N × 6.25) for use in preparing plywood glue.

The first series of pilot-plant meals was prepared from peanuts which were two years old. It was advisable therefore to repeat the tests when a fresh stock of peanuts became available. Results indicate that the age of the seed used has no influence on the gluing characteristics of meal.

Solvent-extracted meal (meal No. 18) can also be used for preparing plywood glue. It is necessary, however, to add oil to the glue made from this type of meal in order to prevent excessive foaming in the spreader.

Influence of Various Factors on the Gluing Characteristics of Peanut-Meal Glue

A satisfactory plywood glue must produce a good joint with the equipment and under the conditions ordinarily encountered in the plywood factory.

The temperature of the glue room and of the water used to prepare plywood glue varies considerably. It was therefore of interest to determine the influence of temperature on the viscosity of peanut-meal glue. The results shown in Table 5 indicate that within the range of 65 to 95 F temperature has little influence on the flow properties of peanut-meal glue.

TABLE 5 EFFECT OF TEMPERATURE ON THE VISCOSITY OF PEANUT-MEAL GLUE

Temperature at which glue was prepared and held, F	Viscosity, MacMichael degrees Wire No. 26			
	1/2 hr	1 hr	2 hr	4 hr
65	50	62	66	76
77	53	59	75	76
85	62	72	86	77
95	59	72	82	71

TABLE 6 EFFECT OF AGE OF THE PEANUT-MEAL GLUE MIXTURE ON PLYWOOD SHEER STRENGTH

Age of glue, hr	Plywood shear tests: Dry strength, psi Wood failure, %	Wet strength, psi
1	405–25	132
2	407–14	128
3	392–10	115
4	396–14	104

The influence of the age of the glue mixture on the results obtained with a peanut-meal glue is shown in Table 6. Test panels were prepared with the glue at the end of 1, 2, 3, and 4 hours. The wet strength obtained was somewhat low to begin with and decreased to some extent with age.

In the manufacture of plywood the glued veneer is stacked until a press load is accumulated, an operation usually requiring 10 to 20 minutes. If a glue is too fluid, an excessive amount may be absorbed by the wood during this period or an excessive amount may be squeezed out when the glued veneer is placed under pressure. If the glue is too viscous, absorption of water by the wood may lead to the production of a dry joint, with the result that a thick film of glue and a weak bond are obtained. The influence of the closed assembly time on the strength of the bond obtained with a typical peanut glue is shown in Table 7. The results indicate that an assembly time up to 15 minutes gives a strong bond. This is an acceptable assembly period.

The yellow birch used for plywood tests varies considerably in color, from white through yellow to red, depending on whether the veneer is cut from sapwood or from heartwood. Since the color of the wood to be used in tests is not specified in the literature, it was of interest to compare woods selected for color, and at the same time to determine the influence of pressure on joint strength. The results given in Table 8 indicate that joint strength is not appreciably influenced by variation in veneer color or by variation of pressure within the range ordinarily applied.

TABLE 7 INFLUENCE OF CLOSED ASSEMBLY TIME ON PLYWOOD SHEAR TESTS

Comparison of Peanut-Meal Glue With Other Water-Resistant Glues

A comparison was made of the results obtained with peanut-meal glue and those obtained with other water-resistant glues as shown in Table 9.

It was also of interest to prepare test panels with tupelo and red-gum woods in addition to the usual birch panels since these two southern hardwoods and Douglas fir are used in the greatest amounts for the manufacture of veneers in this country. The relative amounts (thousands of feet, log scale) of these woods consumed in 1937 for the manufacture of veneers was: Douglas fir 306,299, red gum 213,654 and tupelo 170,438 (18).

An examination of Table 9 reveals that peanut-meal glue is equal to soybean-meal glue when tested according to the official birch-plywood test and also when tupelo and red gum are used. Although the results reported in this investigation appear to indicate that the peanut-meal glues tested are slightly superior in most cases to the soybean-meal glues tested, the number of soybean-meal glues examined is too small to justify concluding that there is any significant difference in these two oilseed-meal glues. It is also probable that optimum conditions were not always employed in gluing the three woods with the two glues. The casein glue examined as well as the mixture of casein, blood, and soybean meal are in most instances superior to the oilseed-meal glues.

The satisfactory results obtained by gluing tupelo and red-gum veneers with peanut-meal glue and the proximity of these southern hardwoods to the raw material for preparing peanut-meal glue presents an opportunity of mutual advantage to southern agriculture and the southern plywood industry.

Influence of Added Blood Albumin and of Hot-Pressing on Peanut-Meal Glue

Blood albumin is sometimes added to soybean-meal glues to increase their water resistance. Glues with or without added blood may be heated in hot presses after the glue joint has been prepared in the usual manner by holding the glued product under pressure for several hours. Therefore preliminary tests which show the effect of hot-pressing at two temperatures and the effect of adding blood to peanut meal, as shown in Table 10, may be of interest.

Hot-pressing of plywood prepared with peanut-meal glue at 180 F has little effect, but raising the temperature to 240 F in-

Wet strength psi	177	232	260

[a] Plywood dried overnight at 150 lb per sq in. pressure and subsequently hot-pressed at 150 lb per sq in. for 10 min at the temperature shown.
[b] Formula given in Table 3.
[c] Formula given in Table 3 with exceptions noted.

creases both the dry and wet plywood shear strengths. The addition of 10 and 20 per cent of blood albumin to the peanut meal increases the shear strength both before and after hot-pressing for 10 min under 150 lb per sq in. pressure at 180 and 240 F. In each case the panels were held at 150 lb per sq in. pressure overnight before they were hot-pressed.

The presence of blood albumin increased the viscosity of the glue considerably thus making it necessary to increase the amount of water; at the same time it decreased or eliminated the need of tetrasulphide.

Plant-Scale Formula and Details for Preparing the Glue Mixture

The formula recommended for preparing plant-scale batches of peanut-meal glue is as follows: The ingredients are added in the order listed:

Water, 200 lb
Peanut-meal flour, 100 lb
Add flour to water and stir to a smooth paste. Then add
Water, 55 lb
Hydrated lime, 15 lb mixed with 35 lb of water
Caustic soda, 4 lb dissolved in 11.5 lb of water
Tetrasulphide (equal parts carbon disulphide and carbon tetrachloride) (1 qt) 3 lb
Stir for 2 minutes and add silicate of soda (Philadelphia "N" brand or equal), 15 lb. Stir for a few minutes and use.

A spread of about 150 pounds of wet glue per thousand sq ft, 3-ply basis, and a pressure of 150 lb per sq in. is satisfactory for gluing plywood.

The foregoing formula is for application to dry hardwood veneers. It may be necessary to alter the water content of the glue when gluing softwood veneers or wet veneers.

Peanut-meal glue was tried on a plant scale in a commercial plywood factory. The glue performed well throughout the process and gave as good or better joints with poplar and black-gum veneers as did soybean-meal glue which was used under the same conditions on the same lots of veneer.

Summary

Specifications have been developed for peanut meal which is suitable for use in preparing plywood glue.

A glue mixture has been developed which has good flow properties and which is accommodated to ordinary gluing schedules for this type of glue. Joint tests show that the peanut-meal glue meets the requirements established for casein and casein-type glues.

Acknowledgment

The authors wish to express their appreciation to the Raymond Pulverizer Division, Combustion Engineering Company, Inc., Chicago, Ill., for grinding and sizing sufficient peanut meal for plant-scale tests, and to the Mississippi Plywood and Veneer Company, Fernwood, Miss., for making trial runs in their plant.

Locomotive Fuel From the Coal-Man's Viewpoint

By C. F. Hardy[1]

The sizes of coal for locomotives and the preparation of coal, screening, and segregation are discussed in this paper. It is suggested that from an engineering standpoint coal specifications for locomotives should be standardized because of the changes in equipment and construction, and that extensive tests should be made.

When the credit for winning World War II is apportioned a large share will be given to the coal-burning steam locomotive. With a tremendous task to do, using to a large extent different sizes and types of coal from those that were formerly furnished, the railroads were able to keep the nation's freight and passengers moving. Probably no other major coal user had so much dislocation of normal coal supply as did the railroads. Of necessity a great part of the coal which could be used for by-product, special purposes, or domestic use, was taken out of railroad fuel and replaced in the main by smaller sizes or lower quality. It is doubtful if any other type of fuel-burning equipment than the steam locomotive could have been operated under such adverse circumstances.

Now that the war is over, the possibility of improving sizes, type, and preparation of the coal for locomotive use is again pertinent. There have been tremendous advances in the practices of coal preparation and coal cleaning in recent years. From the simple bar screens of a few decades ago, coal-screening plants can now produce any practical size of coal. Along with this trend of sizing coal has come the study of its impurities and the best methods of removing these. Some coal-producing districts have installed more cleaning plants than others. This trend has been reflected in the type of coal furnished for locomotive use from these producing districts. These questions naturally arise: Why cannot all railroad coal be standardized as to size and preparation? Is it feasible for either the railroad or the coal industry to standardize locomotive coal? Will it help the performance of present or future locomotives?

The economics of the problem are bound up with the well-known interdependence of the railroads and the coal industry. A few details will suffice to show this interdependence. The railroads are the coal industry's best and most consistent customers and have bought during the last decade approximately 21 per cent of the total annual coal production. The railroads, by purchasing sizes which are temporarily not in demand, have permitted many mines to keep in regular production, whereas otherwise they would have to operate sporadically due to the lack of markets for one or more sizes. This effect is also shown by the fact that the monthly stocks of coal which the railroads carry have varied from month to month as much as 40 per cent, plus the fact that they buy widely varying sizes of coal. The other aspect of the interdependence is that the coal industry is responsible for supplying the railroads with 20 per cent of their total gross freight revenue in normal years and more than 80 per cent of the railroads' total annual fuel requirements.

Contributed by the Fuels and Railroad Divisions and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.

Sizes of Coal Now Used and Recommended for Locomotive Firing

A complete analysis of sizes of coal used by locomotives entitled "1937 Railway Locomotive Fuel" (1)[2] was prepared by the former Bituminous Coal Division. Two hundred and fifty-two different size designations were shown in this report. A less elaborate compilation was made for 1944 and apparently it agrees fairly well with the 1937 figures. In 1937, 445 railroads used 89,935,580 tons of bituminous coal for locomotive fuel. This tonnage represented 82.6 per cent of all locomotive fuel, including fuel oil, anthracite, and wood. The coal came from all but one of the 23 coal-producing districts set up by the Bituminous Coal Act of 1937. (See map.)

Table 1 shows the amount of on-line, off-line, lake, tidewater, truck, and river, total railroad fuel, and the percentage of the districts' production going to railroad fuel. Of the major producing districts, District No. 7, Southern low-volatile, showed the smallest percentage (1.8 per cent) used for locomotive fuel.

Table 2 gives a breakdown by size groups of the total of all districts and of the six largest railroad-fuel-producing districts. From this table it is seen that run of mine and resultant run of mine of more than 4 in. top size are used to a larger extent than any other size coal both off-line and on-line. Off-line locomotive coal is bought on the open market and in this case the railroad has no specific interest in the coal producer. The railroad is free to specifiy the size it regards best for locomotive performance. In spite of this, there is little difference in the sizes bought off-line and those bought on-line. This total, 52,618,116 tons, is almost $6^1/_2$ times as much tonnage as is in the next-larger-size group. Also, more of it is produced for locomotive fuel than any other size in each district, except District No. 11, Indiana. (See first line of Table 2.)

Table 3 is included to show the comparison of the amount and sizes of locomotive fuel produced by each of the foregoing six districts and also District No. 9, Western Kentucky. The size groups of coals were fairly consistent with the run-of-mine sizes showing the largest increase.

In view of the recommendations in the literature for modified screenings or screenings with part of the fines removed, it is surprising that only about 492,000 tons out of the 6,700,000 tons of screenings were modified. (See second line of Table 2.) Even if the size listed as "nut" (see tenth line of Table 2) which might better be included as modified screenings, were included, it would bring the total up to only about 7,500,000 tons. The widespread use of mine run is substantiated by a series of tests run at the University of Illinois in 1917 which showed that mine-run coal (actually 5-in. resultant) is best suited for locomotive use. This series of tests also showed that 2 × 3-in. nut gave good evaporation at high rates and the lowest cinder loss (2).

Zern (3) and Robinson (4) show agreement fairly well on 5-in. or 6-in. resultant mine run with a limit of 23 per cent of minus 1 in. or $^3/_4$ in. Woodrich (5) advocates that the coal supplied for hand-fired locomotives should be of plus $1^1/_2$ in. or 2 in. when it leaves the mine. He states that the use of these coals would stimulate the coal producers to greater efforts in moving the

[b] 1944 Data from Mineral Market Report, M.M.S. No. 1289.

minus $1^1/_2$-in. or 2-in. sizes. For stoker-fired locomotives, Woodrich recommends an average of 3-in. top size, with no lumps more than 8 in. maximum, and a bottom size of $^3/_4$ in.

The International Railway Fuel Association, and likewise the Railway Fuel and Traveling Engineers Association, have devoted much time to the subject of coal sizes (6). In 1942 the R.F.T.E.A. committee on coal sizing recommended run of mine with lumps reduced to 4 in. top size as the most economical size for use on hand-fired locomotives. For stoker-fired locomotives not adapted to handle smaller sizes, "properly cleaned coal not to exceed $2^1/_2$ in. × 0 in." was recommended as the most economical size. For stoker-fired locomotives properly fitted to handle small sizes, 2 in. × 0 in., or coal with a smaller top size, was recommended. It was pointed out that minus $^1/_4$-in. slack was objectionable, particularly in the softer bituminous coals. One-quarter-inch screenings should not exceed 35 to 40 per cent of the total when small sizes are used, according to this committee.

In 1943 the same committee recommended the use of mechanically cleaned coal because it gave the most efficient and economical performance. The principal basis of this recommendation was the experience of a railroad using coal largely from Districts Nos. 10 and 11, Illinois and Indiana.

TABLE 4 STEAM LOCOMOTIVES IN SERVICE OF CLASS 1 RAILROADS
December 31, 1943[c]

	Per cent	Total	Freight	Passenger	Freight or pass.	Switching
Total in service (A) (B)	100	39,498	24,353	6,399	1,738	7,008

No. installed bet. Jan. 1, 1944, and Dec. 31, 1944		329[d]				

NOTE (A) 15,734 of these locomotives are equipped with stokers.
NOTE (B) As of March 31, 1945, 39,658 locomotives were in service of Class I switching and terminal railroads. 21,710 were listed as freight, 6318 as passenger, and 11,630 as switching.
[c] Compiled by Traffic Department, National Coal Association, from American Association of Railroads, and Interstate Commerce Commission figures.
[d] No breakdown available.

The coal specifications set up by the various railroads are not standardized. Each road has its own specifications for locomotive use and these vary widely as to the sizes considered most suitable. Some roads may have facilities to further prepare the coal before using although the author has no data on this subject.

From the engineering standpoint, standardization of coal specifications for locomotives would seem necessary for the following reasons:

1 New locomotives, embodying fireboxes of different designs and different types of coal-burning equipment, etc., have replaced the older locomotives.

2 The older locomotives have been changed by the addition of stokers, different-type grates, arches, front-end design, etc., so that the former sizes of coal are not satisfactory.

3 Experimental and testing work on locomotives has proved that the size of coal should be changed for greater efficiency and economy.

The age and class of service of locomotives now in use are shown in Table 4. About two thirds of the steam locomotives in service were built before 1919 which would seem to rule out condition No. 1. These tabulations show that approximately 40 per cent of the present locomotives are equipped with stokers, although the relative age of the stoker-fired locomotives is not given.

That a great deal of work has been done on grate designs, arches, and "the combustion train" generally, is shown by the literature. There is no indication that these improvements have necessitated the change in sizes or types of coal, but every indication is that they have resulted in burning the present sizes and types more efficiently. The reduction in consumption of coal per ton-mile shown each year is due partially to these improvements, although increased steam temperatures and pressures, improved bearings, roadbed improvements, and fewer and longer trains have also helped.

The experimental and testing work in locomotives quoted in the literature is all of considerable age, although the types and sizes of locomotives tested are still in service. Undoubtedly other work has been done that has not been reported so that the answer to our third condition is not readily apparent.

The Preparation of Coal

The basic mining and preparation practices which have developed over a period of years in the various coal-producing districts have a vital bearing on the extent to which locomotive coal could be standardized without a serious dislocation of the coal industry's economy. Coal is a natural product and varies in quality, size consist, and chemical make-up, not only according to the mining district, but according to the mine and even from the part of the mine from which it comes. It can be improved or modified to a certain extent by mining methods and after it is mined, but no major changes can be made.

In 1943 there were, in the United States, 6620 mines, each having a production capacity of more than 1000 tons of bituminous coal per year. It is therefore difficult to treat the product of so many mines as one subject. No one mine, seam, or coal-producing district could conceivably furnish all the railroad coal in the country, so that of necessity the same locomotive will have to burn coals from widely separated geographic sources, and with different qualities and burning characteristics. The growing practice of running a locomotive over two or more divisions may result in using coals of widely different sources and characteristics on one trip.

If coal is loaded by hand, face preparation is practiced, that is, rock, bone, slate, and other impurities are not loaded with the coal but are rejected by the miner. This is much easier to do with hand-loaded coal than when the coal is mechanically loaded, inasmuch as a loading machine has no judgment as to what it picks up. The same is largely true of "strip" coal, for in strip-mining there is less chance to inspect the coal.

Once the coal is delivered to the tipple, it can be cleaned in two ways: The first and most universal practice is hand-picking, or removing the visible impurities manually. Sizes as small as 1 in. bottom size can be picked, although it is not generally economical to pick sizes under 3 in. The reduction of impurities by hand-picking depends to a large extent on how the impurities are found in the coal, the number of pickers employed, and their efficiency. In many mines hand-picking does not lower the ash content to a great degree, while in many others, where conditions are favorable, a large reduction in ash content is made. It also tends to waste considerable coal if the pickings are not cleaned by washing afterward (7).

It is difficult to pick run of mine and resultant, and it is the practice in some mines to separate into the various sizes, hand-pick or otherwise clean these, and then recombine them.

The second method, mechanical cleaning of coal, has been steadily increasing in popularity. One method of mechanical cleaning consists simply of "dedusting" or screening out a part of the fines and it is practiced in mines where a large percentage

of impurities are found in the extremely fine coal. The top size of coal removed may be as small as 60 mesh and as large as $^1/_4$ in. Of the 590,177,000 tons of coal produced in the United States in 1943, 145,575,849 tons, or 24 per cent, were mechanically cleaned. Of this total, 85.8 per cent or 124,374,775 tons were cleaned by wet-washing, whereas 21,201,074 tons, or 14.2 per cent, were cleaned by pneumatic methods. Forty-seven per cent of the washed coal was cleaned on jigs and 29.6 per cent was cleaned on launders and upward-current classifiers. Of the total coal cleaned, 30,326,426 tons were mined from strip pits, 125,313,687 tons were mechanically loaded underground, and 67,258,305 tons were hand-loaded underground.

Both the wet-washing and air-cleaning processes depend on the difference between the specific gravities of the coal and the impurity. The specific gravity varies for both the coal and the impurity. The "gravity" of the cleaning medium must be adjusted to remove as much of the impurity as possible without wasting excessive amounts of coal.

Although it is impossible to remove organic sulphur or some of the finely divided pyritic sulphur from coal by washing, it is sometimes possible to reduce other types of sulphur in high-sulphur coals by more than 50 per cent, depending on the efficiency of the washer, the nature of the coal, etc. The ash in high-ash coals may be reduced nearly 50 per cent, depending on the distribution of the ash-producing constituents, friability of the coal, etc. (8).

Air-cleaning of coal is usually confined to the sizes which are too small to be satisfactorily wet-washed because of the increase in moisture content likely to result from washing fines. For example, at a given mine sizes larger than 5 in. may be hand-picked, sizes between 5 in. and $^3/_8$ in. washed, and the $^3/_8$-in. $\times$ 0-in. cleaned pneumatically. When all the coal from, for example, 2 in. down is air-cleaned, it is carefully separated into its component sizes before being air-cleaned. For example, if it is desired to clean 2 $\times$ 0-in. coal, it is divided into 2 $\times$ 1 in., 1 $\times$ $^3/_4$ in., $^3/_4$ $\times$ $^1/_2$ in., $^1/_2$ $\times$ $^1/_4$ in., and so on, and run over separate air-cleaning apparatus. It is difficult to air-clean sizes with wide variations, such as 2 in. $\times$ 0 in., in one cleaner.

Mechanical cleaning is necessary and most beneficial to coals containing in the raw state a high percentage of ash and foreign matter and to mechanically loaded coal. Ordinarily when operations in an underground mine are changed from hand loading to mechanical loading, there follows an increase in the percentage of ash in the coal. When a cleaning plant is put in at the same time, the net over-all effect would be to perhaps lower the ash content by one to three per cent over the average encountered in hand-loading methods. The fact that a coal has been washed or air-cleaned is no indication of its quality, as the raw coal from one seam may be superior to the washed or cleaned from another.

The average cost of cleaning is given by Campbell (9) as about 20 to 25 cents a ton. There is an economic limit to the amount of ash and sulphur reduction which may be made by cleaning. Above this, reject losses increase to such a point that it is no longer economically justified to clean it.

Screening Coal

The equipment of mines for screening and preparing coals varies from mine to mine. This depends somewhat on the size of the mine, the amount of coal in reserve or the prospective life of the mine, and on the ultimate use for which the coal is best suited, or those sizes which will return the greatest over-all realization. The problem of screening the coal as it comes to the tipple into those sizes which are most in demand and provide the greatest return for the combination of sizes made is complex and requires both careful study and extensive planning. For example, if the coal from a given mine possesses the peculiar characteristics which make it suitable for domestic stoker coal, it may be profitable to crush some larger sizes to make stoker coal, and not at all profitable to make locomotive fuel.

Mines with no screening facilities of necessity make run-of-mine coal; and mines equipped with bar screens only are able to make two sizes such as 5-in. lump and 5-in. resultant. These mines may be equipped with crushers so that coal can be crushed to a given top size. The bulk of the mines which sell coal for many different uses are equipped with shaker screens and in many cases vibrating screens. A large number of sizes may be made by changing the size of the screens, although the number of sizes which may be made at one time at a given tipple depends on the number of tracks and their usage. The average mine probably makes and loads three or four sizes at a time. The elaborate modern tipples, particularly where mechanical cleaning is employed, may make 12 or more sizes simultaneously, part of which are delivered to bins and may be remixed or blended from the bins before loading. Mines which make only one or two sizes of coal are more likely to be found in the eastern area, that is, in Districts Nos. 1, 2, 3, 4, 6, and 8, than it is in Districts in the Middle West, Nos. 9, 10, and 11.

The practice of furnishing a double-screened washed coal such as 6 in. $\times$ 1 in., or similar size, to the railroads, is probably followed to a greater extent in Indiana, District No. 11, (10) (79.3 per cent of locomotive fuel furnished by this district in 1944 was double-screened with a top size of more than 2 in.) than any other producing district. Districts No. 9 (Western Kentucky), No. 10 (Illinois), and No. 4 (Ohio) also furnish considerable coal of this type. It would probably be most difficult for District No. 1 (Eastern Pennsylvania), to furnish sizable amounts of double-screened coals to the railroads due to the relatively soft structure of the coals. District No. 2 (Western Pennsylvania), No. 3 (Northern West Virginia), and No. 8 (Southern high volatile), could furnish a larger amount of double-screened coal and washed coal for locomotive use than is the usual practice. This, however, would only serve to emphasize the difference in quality between these coals and the others which are often used interchangeably on the same locomotive. If these districts were to furnish a double-screened coal, particularly of a smaller top size, it would mean a tremendous investment in screening equipment for many of the mines not now so equipped, and it is doubtful that the resulting small sizes could readily be sold. Many of the smaller mines which now make railroad coal exclusively could not afford to put in screening equipment, because the acreage available to them is limited. Furthermore, if at a normal rate of production a mine will work out within the next four or five years the cost of screening equipment could not be justified.

The remainder of sizes in a commercial mine which customarily produces block or lump, egg, nut, and 2-in., $1^1/_2$-in., or $1^1/_4$-in. nut and slack is not seriously disrupted by making run-of-mine or a resultant size such as 5 in. $\times$ 0 in. for railroad fuel, as the total production is utilized in the one or two sizes made at this time. If the railroads insisted on a given size, such as 5 in. $\times$ 1 in., the mine would undoubtedly have too much of either the large or small sizes at times and would be unable to operate.

Segregation and Degradation

Perhaps the greatest change that can take place between the time coal is mined and used is the segregation of the coal as it is handled. Each time it is dumped or conveyed the larger pieces tend to roll the farthest, as to the outside of the pile, and the smaller pieces tend to stay near the point of dumping. Naturally, as the difference between the top size and the bottom size of the coal increases, segregation also increases under the same conditions of handling. Segregation can be greatly reduced by careful handling, by using nonsegregating chutes and hoppers, by

layer-loading, etc., as well as decreasing the difference between the top and the bottom size.

Segregation is often confused with degradation, and with bad preparation. The user often finds it hard to believe that the fines he discovers in the middle of his coal pile were there when the coal was unloaded, and are not a result of the coal "slacking" or breaking up.

According to Fraser (11) the greatest degradation is in the handling of plus 4-in. lump coal and this amounts to about $4^1/_2$ per cent. There is very little degradation in the handling of run-of-mine, resultant, or screenings, perhaps due to the cushioning effect of the fine sizes. The same authority shows that the percentage of fines in the mine-run coal as delivered from the hard-structured seams found in Eastern Kentucky and Illinois coals is well within the limit set as desirable by several authorities for locomotive coal. All percentages are under 40 per cent. Subsequent handling, such as filling the fuel bins at coaling stations and coaling the engines would seem to increase the percentage of fines but little.

Briquetting

The briquetting of coal for railroad use in this country has been suggested and extensive tests were run by the U. S. Bureau of Mines in 1908 (12). The first tests were run on No. 3 Pocahontas coal both in the mine-run form and briquetted. As would be expected from the burning characteristics of this coal, the briquettes worked out much better than did the mine run, primarily due to the smaller amounts of fines. Later, briquettes were tried from a wide number of coals and general improvement in burning rates were reported. Apparently then, as now, the higher cost of the briquettes as compared to the cost of raw coal made their use uneconomical. Further research in briquetting methods may in time reduce the processing cost to a more practical figure.

Conclusions

Railroad locomotive fuel is such a large part of the total coal production of the United States that one standard size could not be screened out of the coal as mined without changing the sizes of coal furnished to all other coal users. The mere elimination of all the fines below a certain size would immediately lead to the accumulation of tremendous tonnages of this coal which could not be sold in a normal market.

The present practice of furnishing mechanically cleaned or double-screened coal for locomotive use is confined primarily to those districts where the practice of cleaning has grown over a number of years, due to greater mechanization of the mines, and to some extent to the large amount of impurities in the raw coal. Mechanical cleaning of coal has been developed to a greater extent in some districts and this naturally has resulted in a greater proportion of the locomotive fuel being cleaned. It is true that the trend is in the direction of more careful sizing and cleaning of coal, but it is equally true that all coal mines cannot be changed over immediately to produce a standard size of locomotive fuel. In many cases the raw run-of-mine or resultant sizes from one district will be equal or will be superior to the cleaned or double-screened sizes from another so that there may not be an actual advantage in having the size standardized.

No other type of coal-burning equipment is capable of being operated with such a wide range of size and quality of coals as the coal-fired locomotive. This has helped both the railroads and the coal industry but has also allowed in some cases the buying and furnishing of inferior quality and preparation when better grades were available.

In view of all the factors involved, it would seem that extensive tests should be made, using the different types and sizes of coal in the various sizes and types of present-day and new locomotives so as to determine the best performance under road conditions with as many sizes and qualities of coal as is possible. The published data are so inconclusive that such a procedure would seem prerequisite to making major changes. There is no question that the coal industry is willing to do anything within its power to arrive at the solution of this very important problem of locomotive fuel.

Discussion

E. D. Benton.[3] The value of coal as a locomotive fuel is dependent upon several factors, (1) size consist, (2) calorific value, (3) price per ton, (4) per cent of ash, (5) ash-softening temperature.

Which one of the foregoing factors belongs in No. 1 position depends on the limitations of the other four. The fact that a locomotive can burn almost anything that is black is legend. This, in turn, has worked to the disadvantage of the steam engine and in favor of the Diesel. The availability or distance which a locomotive can operate is governed in no small part by the fuel it consumes. If the coal is high in ash there is a definite mileage limit when it must either be taken out of service and another engine substituted or it must suffer lengthy terminal delays while its ashpan and fire are being cleaned. If the fusion characteristics of its ash tend to promote slagging of the tube sheet, the engine is limited in mileage and must be taken out of revenue service, its fire killed and the honeycomb removed. It is often possible to favorably alter slagging difficulties by the use of double-screened coal or limiting the amount of smaller sizes and extreme fines. However, double-screened coal, after passing through storage piles and the resulting multiple-handling, suffers considerably in size consist by the time it reaches the stoker conveyer screw.

Motive power is a tool and its value is measured by the amount of revenue-tons of freight or passenger-car-miles hauled. This sounds like a trite statement, but let us expand it a little further. In the case of coal traffic, the tonnage moved from the mines depends on the ability of the coal mine to produce and sell its product. In normal markets, production capacity is usually in excess of market demands, resulting in mines not producing because of "no bills" on certain sizes. If the railroads are able to step in

[3] Assistant Supervisor, Fuels Division, Battelle Memorial Institute. Columbus, Ohio. Mem. A.S.M.E.

during stress periods and purchase such sizes as to relieve the bottleneck of no bills, then the sizes in demand move to market and the locomotive produces revenue. By and large the railroads take advantage of the steam locomotive's ability to burn a wide variety of coal by purchasing coal sizes not readily marketable. Thus the steam engine as a tool may be evaluated in two ways. There are, of course, limiting circumstances which may alter the ability of any railroad in the purchase of certain sizes.

The number of hand-fired engines and coaling facilities are the principal reasons why mine run or resultant mine run are purchased in such large quantities. Many railroads are unable to separate coals from various producing districts or certain sizes for specific services. Undoubtedly all producing districts would like the top size decreased but appear to be unwilling to do anything about the bottom size. Skimming the cream off the top simply decreases the availability of steam engines, promotes increased maintenance costs due to cinder cutting, tube-sheet slagging, etc., because when the per cent of small-size coal increases, it in turn causes increased carry-over and finally results in an increase in pounds of coal per ton of freight or passenger-car mile. Whenever you increase cost and decrease availability you simply give the Diesel the "green light."

Because of the way railroad fuel must be purchased and the general policy of storing coal during times of slow market demand, individual coals lose their identity in storage piles and its size consist suffers. But if there are not excessive fines due to the top size being sufficiently large when the coal is received for storage, then the coal from storage to the engine tank will contain less fines in spite of the degradation in storage. One thing which is not changed in storage is the amount of impurities in the coal. It would seem to the writer, since ash is the principal "hurdle" which coal must overcome, that rapid attention be given cleaning plants. If coal had no ash there is considerable doubt whether the now competing fuels would be much of a factor. As the per cent of ash increases, more and more difficulty is encountered until, as a practical matter, one of the measures for the distance coal is able to move from the mine is its per cent of ash. If the coal industry could supply the railroads with coal of not over 8 per cent ash it would have a marked influence on increase in availability and decrease in cost of operation. Another thing which the coal industry might well undertake is the active research of an economical method of drying washed coal. Wet coal in cold weather is particularly troublesome and if the removal of surface moisture could be accomplished economically the coal industry would make an outstanding contribution, not only for the railroads but industry in general, and the coal indusdustry in particular.

E. C. Payne.[4] Mr. Hardy has made some good suggestions in his paper and the writer appreciates this opportunity to emphasize those recommendations which will improve the competitive position of the coal-fired steam locomotive.

It has been proposed that extensive tests should be made using different types and sizes of coal for optimum performance on various types of locomotives. In the writer's opinion such a program should be undertaken as soon as possible so that present locomotives will reach the ultimate in efficiency and reliability and the railroads may find it less attractive to consider other types of motive power. If it should develop that prepared sizes are superior to run-of-mine, it would require a gradual change in the distribution of bituminous coal. Mines without screens would be forced to make substantial investments for tipple improvements, but this would certainly be in keeping with the times, in order that a producer meet all types of competition with coals of similar character. Considering the standardization of sizes for locomotive fuel, it is quite probable that top and bottom sizes should be adjusted to compensate for differences in physical and performance characteristics of the coals from different seams and different mines. The test program should establish the proper size for best performance. The old policy of supplying the railroads with run-of-mine and surpluses of any screen size, as a matter of convenience to the producer, undoubtedly has been a contributing factor in the failure to get the best results from the steam locomotive. Even the most expert fireman cannot obtain the best results unless he is furnished a reasonably uniform quality and size with similar burning characteristics for day-to-day operation.

The statistics cited certainly show that the locomotive has been quite versatile in the utilization of practically every size of coal produced by the bituminous industry. This versatility has been accomplished undoubtedly with a substantial sacrifice in efficiency and reliability. The locomotive with all of its limitations of weight, combustion space, and variable performance conditions should not be required to use just any size or grade of coal. It would seem much more feasible to utilize the stationary power plant for wide-range size and quality-coal application instead of using the railroads for balancing the production at the mines. Industrial steam-generating equipment has wider utilization flexibility and there is a definite trend in new power-plant construction toward the use of an even greater range of coal size and quality. Naturally, any change in the distribution of sizes produced by the bituminous industry should be very gradual, but the coal industry should co-operate to the fullest extent in improving the coal-burning steam locomotive.

It would also seem desirable that the coal industry co-operate with the builders of the modern steam-fired locomotives, and the railroads, to give wide publicity to the superior performance results that are being obtained by the modern coal-fired engines. The public should realize that modern coal-fired engines are also pulling modern streamlined trains and that some railroads believe that comfort, reliability, and economy are obtainable with the modern "iron horse." The coal industry must take other active steps to preserve the competitive position of the steam locomotive, analyzing this railroad-fuel business on an over-all economic basis rather than expect any so-called interdependence of the railroads and the coal industry to perpetuate the use of bituminous coal.

Author's Closure

Mr. Benton has brought up a very good point in that railroad fuel loses its individuality after it leaves the mine, so that any change in standards would have to be made system-wide as far as the railroad is concerned, and industry-wide as far as the coal industry is concerned.

I believe that both Mr. Benton and Mr. Payne have made an important point in that all coal preparation should be better, and that more and more coal will have to be cleaned for railroad use. This of course does not get over the hurdle as to the difference in the quality of the coal in the various districts, and the fact that these coals are mixed indiscriminately and used interchangeably many times on the same trip by one locomotive.

Perhaps when and if the suggested series of tests are made, a standard of preparation for each type of coal will be evolved that will somewhat equalize the differences in quality and burning characteristics. Thus the quality of the coal might be standardized to some extent from a performance standpoint although the size actually used would vary widely as to the district and seam involved.

Let us again re-emphasize that the blind changing of standards without such a series of tests would prove nothing but would merely cause a tonnage dislocation without guaranteeing an improvement in performance.

A Failure-Sequence Indicator for Static Test Specimens

By R. W. POWELL,[1] BURBANK, CALIF.

An instrument is described which has been used to determine the location of initial failure in static tensile-test specimens. Its particular usefulness in aircraft structural development is discussed and technical details of its operation are presented.

In airframe design there are basically two major problems, the aerodynamic design, and the design of the structure. The structure must be strong enough to withstand the highest expected loading and still be as light as possible. It has been variously estimated that 1 lb of weight-saving in an airplane is worth from 10 to 600 dollars in additional pay-load capacity. Certainly weight is at a premium, and for this reason structural tolerances and factors of safety or ignorance must be small.

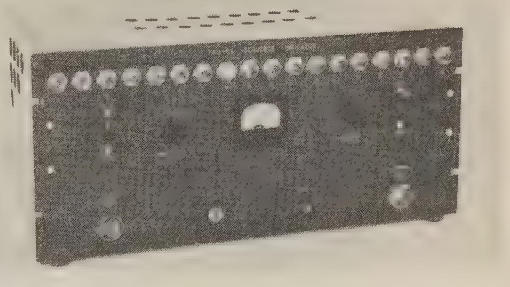
The usual aircraft structure is quite complex so that much of the data for stress analysis must come from empirical tests; and after an analysis has been made it is usually checked by additional tests.

For many years the aircraft industry has used strain gages of various types to obtain much of these data. However, strain gages are useful for measuring relatively small strains over a limited area only, and since the strain distribution in the structure under test is usually the least known factor, it is difficult to be sure that at least one of the strain gages is measuring the highest localized strain. Even if a strain gage is in the proper location and properly oriented, it may not give a good indication for extremely localized strain since a strain gage will average the strain over its active area. Of course, failure, when it occurs, is usually recognizable. However, even after failure, the location of initial failure is not definitely established because an initial failure of a weak section will usually cause progressive failure in adjacent stronger sections due to the resultant redistribution of the applied load.

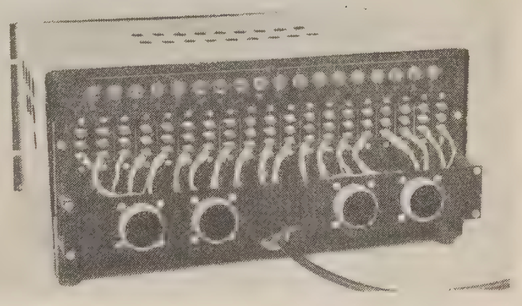
In compression tests the failure is usually in buckling, and in many cases it occurs slowly enough and with enough warning to be easily observed. However, in tension tests in which fracture or actual separation occurs, the failure often gives no warning and can progress, perhaps, at the speed of sound in the material.

For example, in a specimen of 24S-T dural, 3 ft wide, a failure initiated at one side may be complete in as little as 500 microseconds. It is highly desirable to locate the origin of such failures exactly. Ordinary techniques of obtaining data of this nature with the use of high-speed cameras or dynamic strain equipment are not very satisfactory because the interval in which the failure can occur may be from several minutes to several hours, and real difficulties involving film speed and length of film are encountered.

An ideal instrument for this type of measurement should start to record at the instant of initial failure (or slightly before), should be reasonably portable, should be simple to operate and install, and should have no effect on the strength of the structure. The



Front View



Rear View

Fig. 1 Failure-Sequence Indicator

device, Fig. 1, described in this paper incorporates most of these features.

Theory of Operation of the Pickup

The pickup or activating elements of the instrument are composed of small copper wires which are cemented to the surface of the structure. It has been determined experimentally that such wires, when cemented to aluminum alloy, will fail in tension at almost the same time as the structure, Fig. 2, for example. This is true even if the wire is more ductile than the structure, because at failure the wire is constrained by the cement bond at both sides of the rupture, and consequently the strain in the wire is highly localized.

The wire must be small in diameter so that the cement bond will be strong in comparison to the wire. It must be large enough and of proper material so that its incremental elongation will exceed that of the structure. Number 40 annealed copper wire is suitable for incremental elongations up to about 50 per cent, Fig. 3. In practice No. 40 Formex insulated wires are cemented to the structure with Goodyear MN28C cement and are spaced usually not closer than 4 in.

Theory of Operation of the Instrument

There are several possible standard methods of recording sequence of failure of the wires but for the most part they are not suitable because of the indeterminate time of failure or because

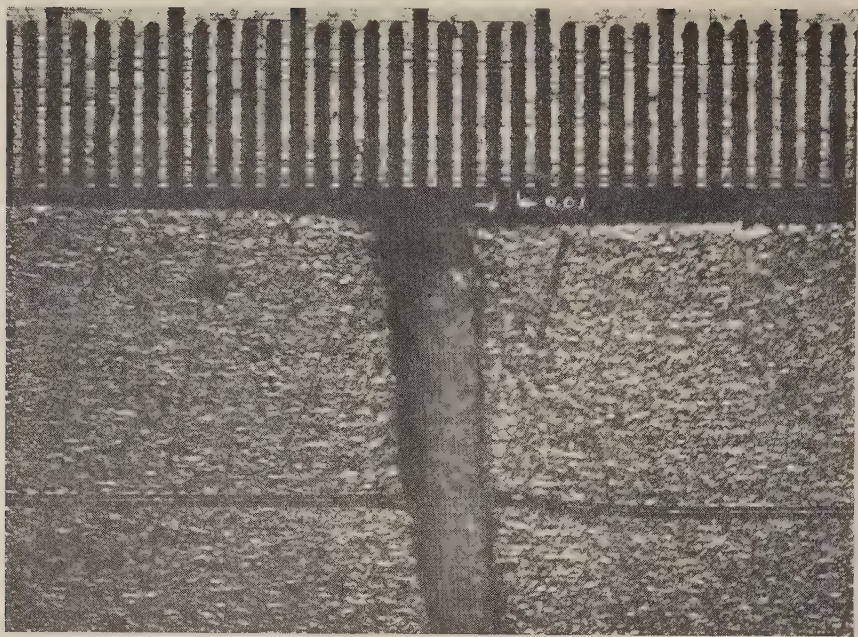

Fig. 2 Typical Failure of Failure-Sequence Wire When Cemented to 24S-T86

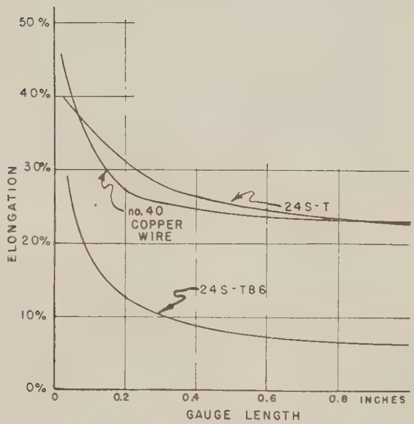

Fig. 3

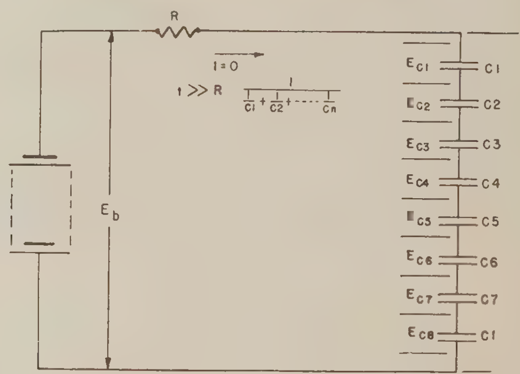

Fig. 4

of the short time involved during failure. The following method, however, has proved practicable:

Consider first several condensers which are connected in series with a battery and resistance, Fig. 4. The sum of the voltages on the condensers is equal to the battery voltage at any time after closure that is considerably greater than the time constant of the circuit. The voltage across each individual condenser is determined by its capacity, leakage, and initial state of charge.

If each condenser is short-circuited by a failure-sequence wire, Fig. 5, the charge on each condenser is zero until the first wire fails, Fig. 6. When this occurs the voltage across the first condenser is

$$E_{c1} = E_b\left(1 - e^{\frac{-t}{RC_1}}\right)$$

At the time of the second wire failure, t_1, it will have a voltage equal to

$$E_{c1} = E_b\left(1 - e^{\frac{-t_1}{RC_1}}\right) = E_1$$

After t_1 the circuit shown in Fig. 6 is modified by the addition of condenser C_2 as shown in Fig. 7. The charging rate of condenser C_1 is changed by the addition of the second condenser. After t_1 the expression for E_{c1} is

$$E_{c1} = E_b\,\frac{e^{\frac{-t_1}{RC_1}}\,C_2}{C_1 + C_2}\left[1 - e^{\frac{(t_1-t)(C_1+C_2)}{RC_1C_2}}\right] + E_1$$

At this same time the second condenser will begin to charge so that

$$E_{c2} = E_b\,\frac{e^{\frac{-t_1}{RC_1}}\,C_1}{C_1 + C_2}\left[1 - e^{\frac{(t_1-t)(C_1+C_2)}{RC_1C_2}}\right]$$

If the condensers are equal in capacity the expressions will be simplified to

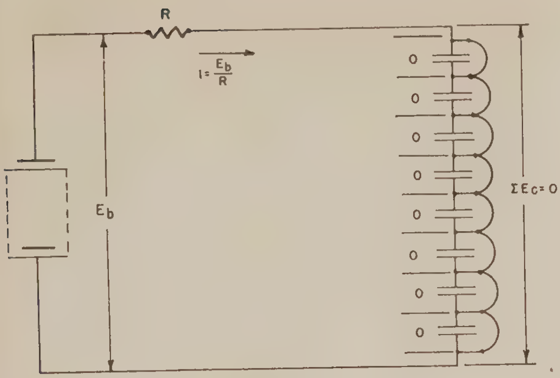

Fig. 5

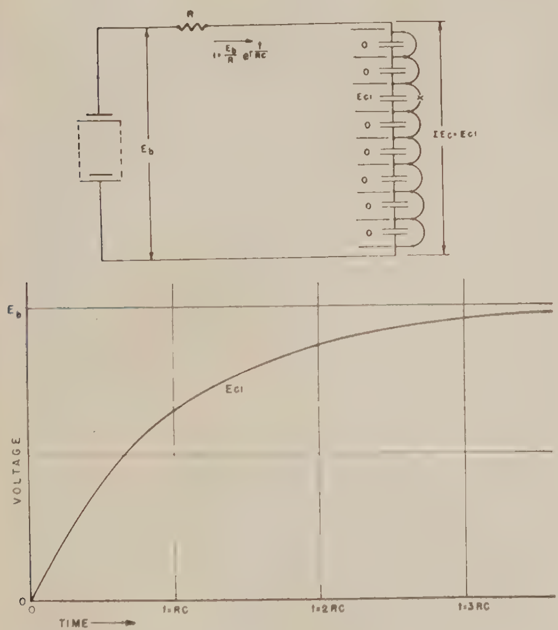

Fig. 6

$$E_{c1} = E_b \frac{e^{\frac{-t_1}{RC}}}{2}\left[1 - e^{\frac{2(t_1 - t)}{RC}}\right] + E_1$$

$$E_{c2} = E_b \frac{e^{\frac{-t_1}{RC}}}{2}\left[1 - e^{\frac{2(t_1 - t)}{RC}}\right]$$

The voltage on each condenser at t_2 when the third wire breaks is equal to

$$E_{c1} = E_b \frac{e^{\frac{-t_1}{RC}}}{2}\left[1 - e^{\frac{2(t_1 - t_2)}{RC}}\right] + E_1 = E_2 + E_1$$

$$E_{c2} = E_2$$

and the equation of charge of each of the three condensers is now equal to

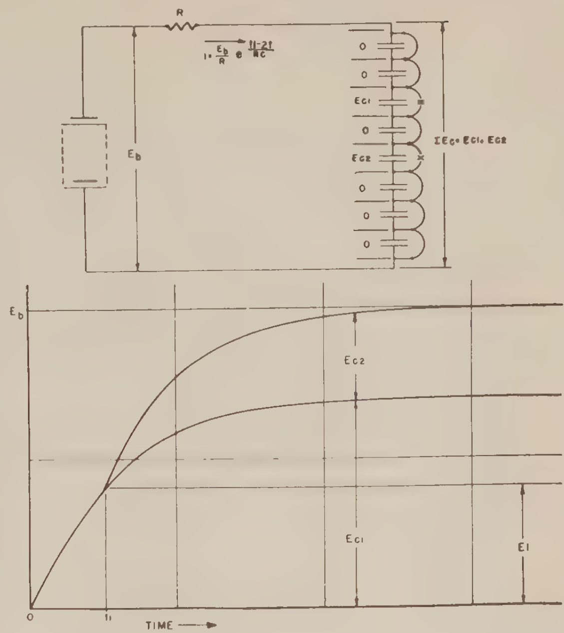

Fig. 7

$$E_{c1} = E_b \frac{e^{\frac{t_1 - 2t_2}{RC}}}{3}\left[1 - e^{\frac{3(t_2 - t)}{RC}}\right] + E_2 + E_1$$

$$E_{c2} = E_b \frac{e^{\frac{t_1 - 2t_2}{RC}}}{3}\left[1 - e^{\frac{3(t_2 - t)}{RC}}\right] + E_2$$

$$E_{c3} = E_b \frac{e^{\frac{t_1 - 2t_2}{RC}}}{3}\left[1 - e^{\frac{3(t_2 - t)}{RC}}\right]$$

and so on (see Fig. 8). It is easy to see that if the condensers are of equal capacity the charge of any one is always greater than that on condensers starting to charge at a later time, and always less than that on condensers that started to charge at an earlier time, Fig. 9. If the leakage is small, the charge on each condenser may be measured after failure by a ballistic galvanometer or a vacuum-tube voltmeter, and the sequence of, and interval between, the failure zones determined.

Unfortunately, it is difficult to keep these leakages small if the condensers remain attached to the specimen and to the battery, Fig. 10. Therefore 10 milliseconds after the failure is complete, all circuits to the condensers are opened automatically so that the slight remaining leakage will merely decrease the charge, leaving the ratios of charge between the several condensers relatively unchanged. The condensers are carefully picked for low dielectric leakage and for uniformity of capacity.

Even with the foregoing precautions the time of recording data manually for a large number of sequence wires could allow excessive leakage. The instrument is therefore provided with an automatic stepping relay that scans the condensers and indicates first failure with a numbered light. Immediately following failure, the scanning relay automatically goes into operation connecting a vacuum-tube voltmeter, which does not discharge the condenser, to each condenser successively. If any condenser has a charge of 80 per cent or more of the applied voltage a relay is actuated, the scanning is stopped, and the corresponding light indicates the location of the first failure.

In case of initial simultaneous wire failures the switch will scan

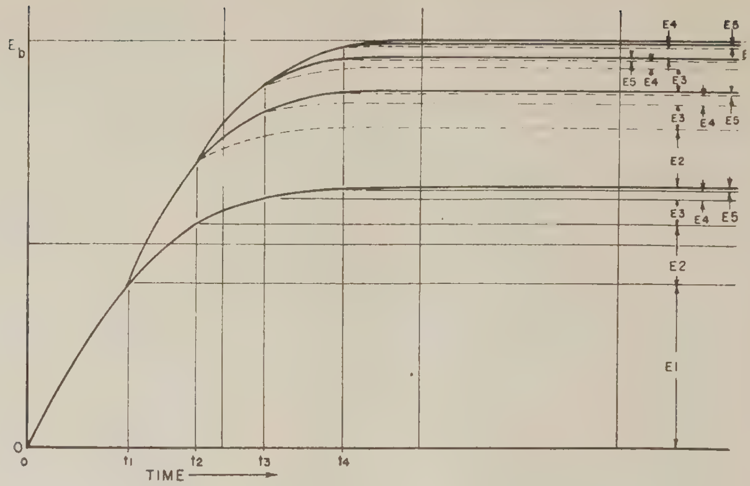

Fig. 8

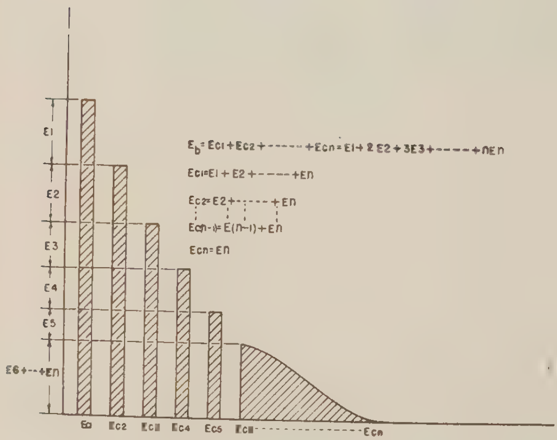

Fig. 9

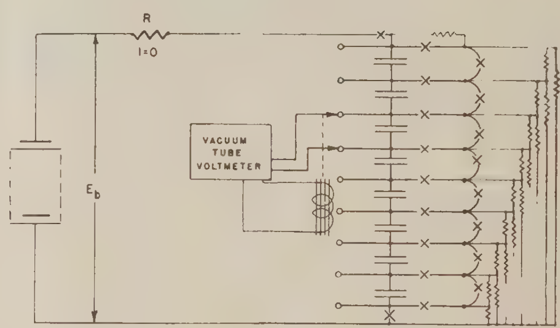

Fig. 10

through once and the operator may increase the voltmeter sensitivity until a stoppage of the scanning relay is effected. The number of the wire is indicated as before by the lights, and the charge on the condenser is indicated by the meter on the front panel. When these data have been recorded the operator may continue the scanning to another stoppage by pressing the "step" switch to restart and adjusting the sensitivity control.

As the instrument is currently used, any number of failure-sequence wires up to 18 may be attached (if necessary, it may be designed for any number of wires). It has an initial time constant of 500 microseconds, which means that a difference in time of failure of 20 microseconds of the first two wires may be detected, or that the second wire to fail may be determined if it occurs as much as 2 millisec after the initial failure. This time range may be changed to other values by changing the size of the resistor or the condensers.

Conclusion

The device has been used on static tests of aircraft structures involving 24S-T, 24S-T86, and plexiglas, and in each instance the data obtained were wholly consistent and apparently valid. In several cases structural redesign was based, in part, on the indications obtained by this method, and improved strength and joint efficiency were obtained.

Laminated Edge Attachment for Acrylics

By E. H. SNYDER,[1] BURBANK, CALIF.

As it had been observed that pressure loads encountered on such large acrylic parts as canopies, astrodomes, blisters, noses, windshields, and the like, caused frequent replacements, particularly at attachment points, it was determined that an improved method of attachment must be developed. In this paper is described an improved method of edge attachment for the canopy of the P-80 airplane in which aerodynamic and cockpit pressure loads have imposed higher loads than usual in the acrylic canopy material. In tests, laminated edging integrally attached to acrylic sheeting consistently approached and in certain cases developed the full strength of the cast acrylic sheeting.

Introduction

An examination of a number of service reports on large acrylic parts such as canopies, astrodomes, turrets, blisters, noses, and windshields revealed that replacements were comparatively frequent. Most replacements were necessitated due to crack formations originating at attachment points. The method of edge attachment assumed a role of increased importance with the introduction of high-performing aircraft such as the P-80 airplane. Aerodynamic and cockpit pressure loads encountered in the P-80 imposed still higher loads in the acrylic canopy material.

The present conventional method of attachment requires the drilling of a considerable number of holes along the edges of the canopy. These holes have to be large enough to permit the installation of rubber grommets and steel liners which serve to minimize the possibility of crack formation. A new and improved method of edge attachment was recently developed which consists of bonding integrally a laminate of relatively high strength to the canopy edges. Attachment can then be made directly through the laminated edge strips without the use of grommets and liners.

Until recently the manufacture of such a reinforced edge has not been practical. However, with the development of catalysts which promote rapid polymerization or solidification of the methyl-methacrylate liquid monomer in the presence of ultraviolet light, the bonding of edge strips to the canopy has become feasible.

Preliminary tests showed that this type of attachment was at least twice as strong as the conventional edge attachment. Thus a series of tests was instigated to develop a design and technique which was commercially applicable to regulation canopies. The final objective of this program was to apply the new attachment method to actual airplane parts such as canopies and windows and determine their strengths when tested under conditions encountered in the actual flight of the airplane.

Discussion of Laminating Resin

The acrylic sheeting used in present-day aircraft is made by casting methyl-methacrylate monomer (a water-white liquid) between two glass plates. The addition of a catalyst and the application of closely controlled heat cause the monomer to polymerize or cure into a solid state. Polymerization is accompanied by an exothermic reaction, which, if not properly regulated, would cause the rate of polymerization to progress beyond control and result in the formation of bubbles or perhaps violent boiling of the monomer. This is reviewed in order to point out that polymerization must proceed at a rather slow rate. Several days or a week, depending upon the thickness, are necessary for the curing of the usual cast sheet.

When attention was first directed toward a laminated edging for acrylics, it was conceivable that layers of cloth could be cast integrally around the edges of a cast acrylic sheet. This, however, was beyond the scope of the average aircraft plastics laboratory. It was hoped that a quicker and more practical method could be developed to attach integrally a laminated edging to methyl-methacrylate sheeting.

A light-sensitive catalyst,[2] which caused strips of cloth, impregnated with prepared acrylic monomer to "jell" in 5 to 10 min. and cure into a hard mass in approximately 1 hr of exposure to sunlight, appeared to be the solution to the laminated edge attachment.

Methyl-methacrylate monomer is waterlike in consistency. To make it more suitable for laminating operations, it was thickened or bodied so that it would not run off the laminated or bonded item before the polymerization or solidification reaction was complete. The monomer was bodied or partially polymerized by adding a very small amount (0.2 per cent by weight) of the light-sensitive catalyst and refluxing until the suitable viscosity was attained. Care was exercised in determining the amount of catalyst necessary so that none in excess of the specified amount would be added. Too much catalyst would cause the exothermic reaction which occurs during refluxing to proceed so rapidly that uncontrollable boiling results in complete polymerization. When this bodied resin cooled to room temperature, an additional 3 per cent by weight of the catalyst was added to make it ready for application. In this condition it must be used within a few hours or stored in a refrigerator to prevent complete solidification or polymerization.

Fabrication of Joint Specimens

The test specimens used to determine the strength of the various types of edge attachments were made from $^5/_{16}$-in-thick acrylic sheet stock $4^1/_2$ in. long and 3 in. wide. The thickness and width were thus chosen to approximate 1 sq in. of cross section. The laminates used for the edges of the new type joints consisted of Fiberglas or other fabrics laminated with the same resin that is used for making the actual blown canopy.

Type I—External V-Joint. Some of the first acrylic tension specimens, containing an external "V" on the ends (see Fig. 1) were prepared "wet;" that is, laminae of glass cloth which had just been dipped in the acrylic resin were laid symmetrically on either side of the scarfed ends and the whole assembly sandwiched between cellophane-covered glass plates. After exposure to sunlight for approximately 1 hr, the resin polymerized or cured, and the specimen was then ready for trimming and mounting. It has been found that the time necessary for curing can be substantially reduced by using a good strong source of ultraviolet light instead of natural sunlight.

Since cut Fiberglas cloth tends to fray and become unwoven at the ends, it was practically impossible to keep a few loose glass

[1] Research Engineer, Lockheed Aircraft Corporation.

Presented at the Rubber and Plastics Session of the Aviation Division Meeting, Los Angeles, Calif., June 3–5, 1946, of The American Society of Mechanical Engineers.

[2] Manufactured by C. C. Sachs, No. Hollywood, Calif.

threads from floating out upon the clear portion of the specimen and being cured in place.

To avoid the problem of these loose Fiberglas threads and also the undesirable handling of the wet laminae in the final preparation of specimens, laminates were cured into flat sheets in the following manner:

Each piece of fabric (about 23 in. square) was dipped into a pan of the prepared resin and laid in place on a 2-ft-sq piece of cellophane-covered tempered glass plate. As each piece was stacked on the glass plate the trapped air bubbles were worked out with a suitable squeegee. When all layers were in place, micarta strips $^1/_2$ in. wide and of proper thickness were nested around all four edges to serve as spacers and also to prevent too much resin from escaping. A second 2-ft-sq piece of cellophane-covered tempered glass plate was then placed over the stack of impregnated fabric and clamped in place with a number of standard C-clamps. After curing, the laminate was machined into strips for bonding to the acrylic-specimen edges. These flat laminated sheets were made in thicknesses equal to one half that of the acrylic component in order to facilitate beveling of the edges of strips which were machined from the flat sheets. Figs. 1 and 2 illustrate how the beveled strips were placed together to form a mating "V." The successful rapid machining of these strips was accomplished by using cutting tools with cemented-carbide tips. The prepared resin was placed on all mating surfaces and the strips cured in place by exposing the assembly to sunlight.

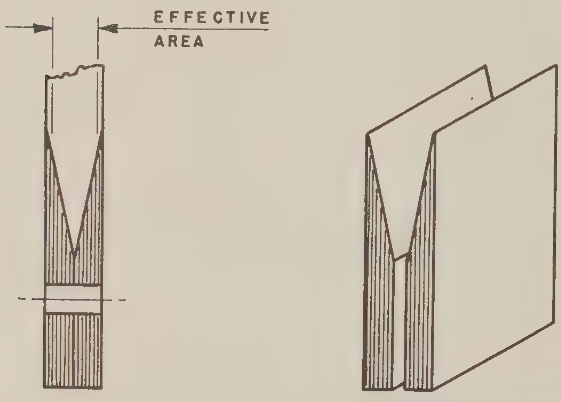

Fig. 1 External V-Joint

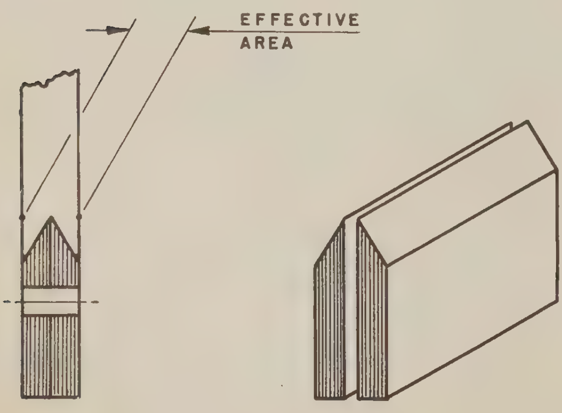

Fig. 2 Internal V-Joint

Tests made on this type of attachment showed that it had a strength equivalent to that made with individual wet laminae but it, too, had some distinct disadvantages: (1) Due to the shrinkage problem which is difficult to handle and because of the fact that resin cast in this manner has a lower strength than the original acrylic sheet, the scarf of the edge strips had to be of a length which would allow a transition gradual enough to produce an attachment of optimum strength. The length of scarf necessary caused the opaque laminated edge to extend about $^1/_2$ in. above the usual canopy mount, thus decreasing visibility. (2) Any excess resin which was present tended to be forced over the clear adjacent surface. This necessitated laborious polishing to restore the original optical qualities.

Type II—Internal V-Joint. This type of joint was also made by bonding the cured laminated strips to the prepared acrylic edge, but in this case the scarfed edges of the laminate were fitted into an internal "V" in the acrylic edge (see Fig. 2). Tests made on this type of specimen showed that it was stronger than an equivalent external type of joint; and that an internal "V" $^1/_4$ in. deep was as strong as any $^3/_4$ in. external V-joint. In addition, the disadvantages of the external type of joint were eliminated, because it was now possible to keep the opaque edge flush with the canopy mount, and any excess resin present when the edge strips were bonded in place was forced over the opaque laminate instead of the clear adjacent acrylic sheet.

Figs. 1 and 2 illustrate both types of joints and clearly indicate the advantages of the internal type of attachment.

Results of Tests

Tension Tests. As a result of stress concentrations, the efficiency of edge attachments in direct tension vary from 30 per cent (for bolted attachments, using rubber grommets and steel liners) to approximately 85 per cent for laminated edge attachments. In terms of average stress at failure, the conventional bolted attachment developed approximately 2500 psi and the laminated edge attachments ranged as high as 6500 psi.

Bearing Tests. Since the specimens containing the laminated Fiberglas edges were failing outside of the actual joint and causing no appreciable elongation of the attachment holes, it was decided that a laminate containing all laminae of Fiberglas was too strong. It was hoped that a laminate of cotton or linen cloth would solve the problem and eliminate the undesirable machining qualities of laminated Fiberglas, but the linen and cotton cloth-filled laminates failed in tension before there was any evidence of bearing failure. A number of laminated bearing specimens were thus fabricated using a combination of cotton cloth and Fiberglas cloth. Elongation of the attaching holes was thereby controlled by substituting cotton cloth for certain Fiberglas laminae.

Fatigue Tests. Test specimens of the conventional rubber grommet-and-liner type and those containing the internal V-type laminated edges were made identical to those used for tension tests. These were tested dynamically at various loadings and frequencies until failure occurred. The fatigue life of the laminated attachment was found to be over 1000 times that of the bolted type.

Applications of the Laminated Edge Attachment

(*a*) *Aircraft Canopies.* From the promising results obtained from the small test specimens it was decided to prepare a full-size canopy of the type used on the P-80 airplane with the new type of edge attachment and tested under simulated flight conditions.

The P-80 canopy is of the one-piece "bubble" type, which lends itself to "free-blowing" or vacuum-forming. In this process of forming, a heat-softened acrylic sheet is clamped to a vacuum pot and free-drawn to a controlled depth. The shape of the

vacuum-pot opening gives the general outline required for the canopy edge. After forming is completed the enclosure is finish-trimmed for mounting.

The P-80 production canopy is fabricated from $^3/_8$-in-thick acrylic sheet. However, the new canopy which was to contain the laminated edging was formed from a $^5/_{16}$-in-thick acrylic sheet.

Following is a step-by-step description of the detailed operations required in the preparation of the laminated strips and their subsequent attachment to the canopy edges:

1 Preparation of laminates: As a result of the bearing tests made on various types of laminates, a combination muslin-and-Fiberglas cloth laminate was chosen, which would show an incipient bearing failure in the attaching holes at a load slightly below the average breaking load of the acrylic specimens. This would allow a more uniform distribution of the loads.

The laminated-edge-strip material, which was considered as the optimum for this type of attachment, consisted of two layers of coarse-woven muslin with a layer of ECC-11-148 Fiberglas cloth on each outer surface. These laminates were made in the same manner as previously described, and their nominal thickness was chosen as $^1/_{64}$ in. less than $^1/_2$ of the minimum thickness of the canopy edge, in order to make it possible to produce a completed edge strip with surfaces flush with the canopy surfaces. The laminated panels were cut into strips $1^1/_8$ in. wide and then beveled on one edge to mate with the canopy edge and also on each end to mate with adjoining strips.

It has been found that the variation in thickness of commercial canopies was as much as 0.100 in. due to manufacturing tolerances; in addition, the thickness variation may further be increased by the canopy drawing or stretching operation. However, by placing a strip of wet uncured resin-impregnated fabric between two cured laminated strips, it was possible to compensate for any variation in thickness normally found.

2 Preparation of canopy edges: The edges of the special blown acrylic canopy were first trimmed shorter than a conventional canopy to allow for the addition of the laminated edge. The edges then were machined to form an internal "V," since the internal V-joint had proved to be superior from the standpoint of strength and ease of fabrication. The internal "V" was machined quite readily by the use of a portable hand router and a special bit.

Transparent contoured fixture strips, which were necessary to hold the laminated edging to the canopy and at the same time permit light to reach the joint to effect curing, were obtained by sawing off the edges of scrap production canopies. These contoured strips were then clamped on either side of the canopy edges so that they extended approximately $1^1/_2$ in. beyond the machined edges of the canopy. They served their purpose effectively for the forming of the laminated strips and also as transparent fixtures for holding the formed laminated strips in place during the curing cycle.

3 Forming of laminated edge strips: The prepared laminated strips were formed to mate with the ever-changing contour of the canopy edges. Since the resin used to make the laminates was a "thermoplastic" (softens under heat and hardens when cooled), it was only necessary to heat the strips for several minutes in an oven at 300 F and then hold them in place in the grooved canopy edges until they cooled. This was facilitated by the transparent fixtures (edges from scrap canopies) clamped to the prepared canopy edges. The hot pliable laminated strips were forced down onto the machined edges of the canopy and clamped to the overhanging transparent fixture strips until they cooled enough to retain their new contour.

4 Curing of preformed laminates to canopy: The next step in the fabrication of the edge attachment was to sandwich a wet resin-impregnated Fiberglas lamina between two cured formed laminated strips to build up the thickness of these edge strips to equal that of the canopy edge. Excess resin from the wet laminae flowed into any spaces created by the varying edge thickness of the canopy and was thus cast and cured into place around the canopy edges to form a smooth, clear, and continuous transition from the opaque laminated edge to the clear acrylic canopy material.

To simplify tooling, the attaching operation was accomplished in two steps. In the first step the cellophane-covered transparent fixture strips were clamped only to the inside edges of the canopy. The chamfered edges of the inboard cured laminated strips were "doped" with resin, forced into contact with the canopy edges, and clamped in position to the fixture strips for curing. The second curing step was taken after removal of the inboard transparent fixture strips. The wet impregnated Fiberglas lamina was then placed on the previously attached inboard laminated strip. Next, the chamfered edges of the outboard cured laminates were doped with resin and carefully placed in their correct position on top of the wet lamina. The cellophane-covered outboard transparent fixture strips were then placed on top of this assembly and clamped in place to the canopy. As a final operation to assure correct positioning, the outboard cured laminates were forced into intimate contact with the machined edges of the canopy before finally clamping in place to the outboard fixture strips for curing.

The canopy described, having the laminated edging, was subjected to pressurization tests along with production canopies containing the rubber grommet-and-metal liner type of attachment. The laminated-edge-type canopy, blown from $^5/_{16}$-in-thick acrylic material, withstood pressurization loads 25 per cent greater than those which produced failure in the $^3/_8$-in-thick production canopies. This $^5/_{16}$-in-thick canopy, containing the laminated edging, was not tested to destruction, but was saved for possible investigation of other variables.

This canopy was actually one of three fabricated with the laminated edging for testing purposes.

The first one, formed from $^5/_{16}$-in-thick acrylic sheeting, failed prematurely at a load higher than that withstood by any previous production canopy, when part of the mounting structure failed.

After reinforcement of the mounting structure, the second $^5/_{16}$-in-thick canopy was tested as previously described and then saved for possible future investigations.

The last and third canopy was formed from $^1/_4$-in-thick acrylic sheeting. Considerable speculation awaited the test results of this particular canopy. Unfortunately, however, it was cracked during installation, so further testing was discontinued.

5 Fabrication of canopy from a flat developed pattern: Near the end of the war an ingenious method was developed by a West Coast plastics fabricator[3] for the free-blowing of aircraft canopies from a flat developed pattern. This method consisted of machining a sheet of acrylic to the exact flat developed pattern of the canopy. After heating the flat blank in a specially constructed oven, it was carefully laid on a blowing jig and securely clamped around all edges to effect a perfect seal against air leaks before the blowing operation was started. Positive air pressure was used rather than pulling a vacuum. This enabled the operator to check the part during the blowing process and control the air pressure throughout the operation.

The canopy for North American's P-51 "Mustang" fighter plane was "free-blown" from a flat developed pattern using this method. With North American's permission a P-51 canopy was secured by Lockheed in the flat pattern, and Lockheed's laminated edge attachment was cured to the edges of this pattern.

[3] Stacks Plastics, Culver City, Calif.

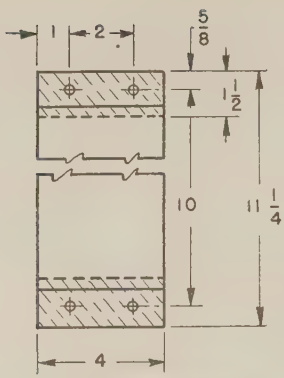

Fig. 3 Creep Specimen

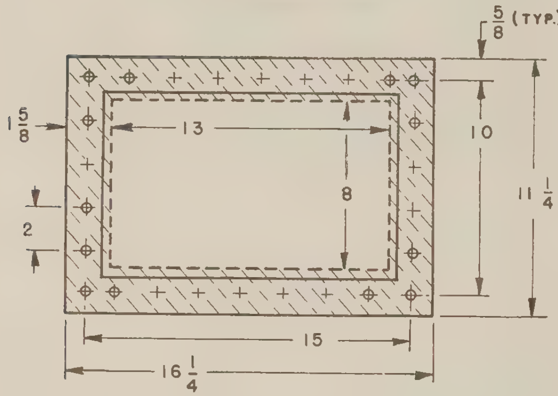

Fig. 4 Shear Specimen

Since the curing of the laminated edge strips to a flat sheet obviously entails less difficulty than curing strips of compound curvature to canopy edges of compound curvature, it was desired to determine whether or not the addition of the laminated edging to the flat pattern would alter the forming characteristics of this particular free-blowing method.

No difficulties were encountered in the final operation of blowing this flat developed pattern into a finished canopy with laminated edges.

The hand methods used in fabricating the special laminates and their subsequent attachment to the canopy edges were necessarily laborious. However, when production methods are considered, it is apparent that certain operations could be eliminated or greatly simplified. The method of blowing canopies from a flat developed pattern would further facilitate production if applied to the laminated-edge-type canopy.

(*b*) *Acrylic Panels.* Since joints of 85 per cent efficiency were consistently being produced of laminated strips to acrylic sheeting and developing stresses as high as 6500 psi, the possibility of using stressed acrylic panels was given consideration.

One of the characteristics desired to be known about an acrylic panel, which incorporated a laminated edge attachment, was its behavior when subjected to shear loads both at normal and extreme temperature ranges.

1 Shear tests. The method used in fabricating the shear test specimens was essentially the same as that used for fabricating the canopy laminated edge attachment. Three test specimens were made from $^3/_8$-in-thick acrylic sheeting according to Fig. 4. These panels were mounted in a steel shear frame having pin-connected corners, and the assembly was attached to a rigid floor structure. The shear loads were applied to the panel frame by means of hydraulic jacks and transferred to the plastic panel through the $^1/_4$-in-diameter attaching bolts. Total shear deflections were measured by means of a dial gage. A temperature-controlled enclosure was built around the test panel so that various temperatures could be accurately maintained.

The first panel was loaded at a temperature of 65 F in increments of 50 lb per in. (see Fig. 5). The application, removal, and reversal of shear load was repeated for 1000 cycles at 150 lb per in.; 1000 cycles at 300 lb per in.; and 3000 cycles at 500 lb per in. This repetition of loading showed no change in the shear deflection noted at the beginning of each cycling test. A maximum static load of 850 lb per in. was applied at room temperature without any serious permanent effects.

When the foregoing tests were completed the temperature was lowered to —55 F, and a load of 300 lb per in. was applied and maintained for 2 hr. Upon removal of all load there was no indication of permanent set. The load was then gradually increased to a maximum value of 650 lb per in., whereupon the specimen suddenly shattered.

The second panel was installed and the temperature lowered to —40 F. Loading was applied in small increments, and again when the value of 650 lb per in. was reached, the panel suddenly shattered.

The third and last panel was tested at 130 F. Loading was applied in 50-lb-per-in. increments until a load of 600 lb per in. was attained. Failure occurred approximately 90 sec after application of the 600-lb-per-in. load.

The amount of deflection at various temperatures is compared in Table 1.

2 Tension creep tests. The purpose of these tests was to determine the behavior of an acrylic panel incorporating laminated Fiberglas edges under prolonged tensile loading at various temperatures.

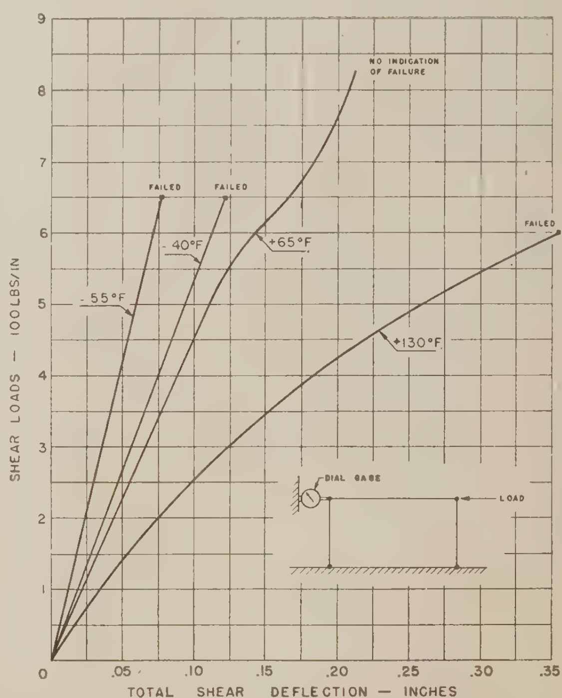

Fig. 5 Shear Load Versus Deflection for Laminated Edge-Acrylic Panel

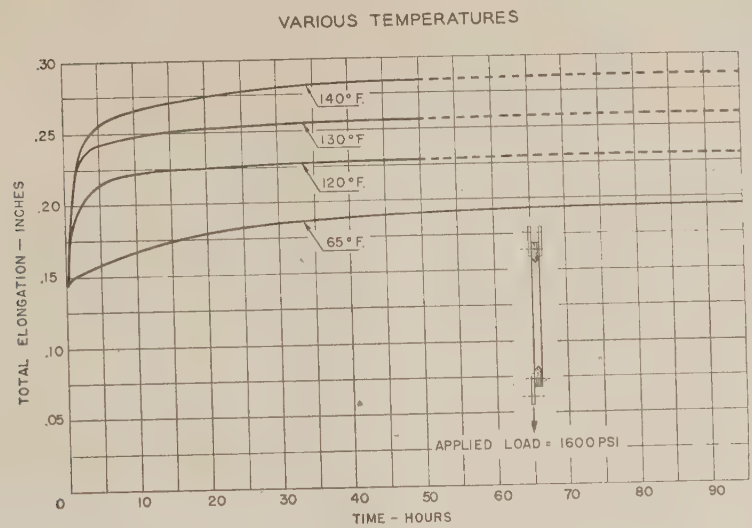

Fig. 6 Acrylic Creep Tests; Elongation Versus Time at Various Temperatures

TABLE 1 DEFLECTION OF TEST PANEL AT VARIOUS TEMPERATURES

Temperature, deg F	Shear load, lb per in.	Total deflection, in.
— 40	650	0.120
70	650	0.155
130	600	0.354

Test specimens were made from $^3/_8$-in-thick sheet stock with the Fiberglas edge attachment at each end, as shown in Fig. 3.

Specimens were suspended in a controlled-temperature enclosure by means of a double-shear-type fitting. At the lower end, arrangement was made for applying 2400 lb (600 lb per in.) through a single shear-type fitting, so that there was an eccentricity of $^9/_{32}$ in. between the suspension and the applied load. Two dial gages, calibrated in thousandths of an inch, were installed, one on either side of the specimen, to indicate the total elongation in the 10-in. gage length. Time versus elongation curves for different temperatures are presented in Fig. 6.

The tests indicated that when the load was first applied the rate of creep was high, but that it decreased rapidly over the first several hours.

Creep effect is greatly influenced by temperature, as may be seen by referring to Fig. 6. Considering 10 hr as a reasonable period for "long-duration" loading, it is apparent that under 600-lb-per-in. load and at room temperature, the observed creep constituted only an additional 12 per cent above the elastic (instantaneous) elongation, while at 140 F the deformation would almost double itself. Under this load and at any temperature up to 140 F, 10 hr appears to be sufficient time for a reasonable stabilization of the elongation.

At the conclusion of the tests no permanent elongation of the holes in the Fiberglas-reinforced edge was apparent. It is improbable that any appreciable amount of the observed creep effect occurred in the laminated edges.

Summary

In summarizing, it is pointed out that a laminated edging integrally attached to acrylic sheeting consistently approached and in certain cases developed the full strength of the cast acrylic sheeting.

Where further reduction in load concentrations is necessary at attachment points, various combinations of filler material may be used in the laminated edging to produce controlled bearing failure in the attaching holes.

Rotational Drop-Testing of Airplane Main Landing Gear

By W. H. GAYMAN,[1] BURBANK, CALIF.

The immediate physical objectives of drop-testing are presented, together with a general method for conducting rotational tests that have proper contact velocity and energy relationships coincidental with the absence of undesirable dynamic reactions at the pivot axis. Application of the method to tests of the main landing gear of the Models PV-1 and PV-2 patrol bombers is discussed. Conclusions drawn from dynamic-load measurements emphasize the possibility of attaining excessive loads in the drag-resisting structure when the impact surface is horizontal and the gear is inclined to simulate resultant loading of any particular design condition. It is implied that the practice of dropping the test gear on an inclined platform during translational drop tests may result in unconservative loading unless deliberate compensation is afforded.

Introduction

DROP-TESTING of a newly designed airplane landing gear is commonly included in the structural-test program carried out with a static-test airplane. These tests have as their immediate purpose the demonstration of the degree of compliance with design specifications regarding, fundamentally, the energy-absorption characteristics and related dynamic behavior of the landing gear. While the tests are generally preceded by landing-gear-jig drop-tests, conducted incident to developing or checking the shock-strut design, their specific objectives are the determination of landing-gear functional characteristics with effects of airframe elasticity included, and the checking of the structural integrity of the gear and its supporting members. The latter consideration is in general complementary to other required structural tests.

In the case of an airplane with conventional landing gear, it has been customary to conduct rotational drop-tests independently for both tail gear and main gear. In tests of the former, the airplane is usually permitted to "rotate about the main gear axles" as the tail is raised and dropped. In tests of the main gear, the tail-wheel axle or some other convenient item is utilized as the pivot axis.

The author has failed to discover any literature justifying the basic concept of rotational drop-testing of main landing gear as commonly executed; he presumes that its acceptance has been due to its advantages over translational drop-testing of the entire airplane because of its inherent freedom from additional test variables arising from the following:

1 The problem of assuring simultaneous or at least reproducible contact conditions of main wheels and tail wheel.

2 Interactions of main landing gear and tail landing gear attributable to airplane-pitching accelerations due to different stiffness rates and strokes of the two basic types of landing chassis.

This is not to imply that translational drop tests are conducted infrequently; the advent of tricycle landing gear has given impetus to development of this technique.

However, it is not the purpose of this paper to present a discussion of methods other than rotational drop-testing, or of the philosophy of drop-testing in general. Rather, the intent is to present, from a test engineer's point of view, a discussion of methods that have been under development since the beginning of a program for drop-testing the PV-1 patrol bomber.

1 GENERAL DYNAMIC CONSIDERATIONS

Drop-Test Problems

There appear to be no standard interpretations of drop-test criteria as they reflect on the major aspects of the physical problem. Consequently, the test engineer must formulate his own interpretations from the pertinent general specifications, or perhaps depart from the letter of the specifications in order to rationalize some of the apparent physical incompatibilities. For example, while the drop-test specifications of various agencies are specific enough in defining "drop-height" and "load-factor" requirements for landing gear of various types of aircraft, in general they either leave too much latitude in the test-airplane weight distribution or impose limitations that have no fundamentally rational basis. In the manner of support of the test airplane at its pivot attachment, a specification may impose restrictions, which, if rigidly adhered to, can unwittingly cause local failure of the aft fuselage section in the attempt to obtain tests of the main landing gear, or conversely, failure of the main landing gear or its supporting structure in rotational drop tests of the tail gear.

That instances of such failures exist is a matter of record. In some cases a "too literal" interpretation of the pertinent specification may have been the cause; in other cases lack of precedent, combined with insufficient appreciation of the dynamic aspects of the problem may have been a factor. In any case, however, possible danger to test personnel as well as direct and indirect costs occasioned by such accidents have warranted the direction of efforts to evolve a practical rotational drop-test technique that satisfies all of the basic requirements. Because of the length that would be required to cover specific problems arising in rotational drop-tests of auxiliary gear, the present discussion is necessarily limited to rotational drop-testing of main gear, although the basic dynamical approach is applicable to either.

Rotational drop-testing is simply a convenient means of obtaining landing-gear performance characteristics. Because of the variation of linear acceleration with distance from the center of rotation, this type of test is not intended to constitute a structural test of the entire airplane, but rather is limited to a relatively localized region embracing the test gear.

Test Setup Parameters

In order to impart a maximum of physical meaning to the interpretation of the test results it is important that the test setup

[1] Formerly, Research Engineer, Lockheed Aircraft Corporation.

Presented at the Aviation Division Meeting, Los Angeles, Calif., June 3–5, 1946, of The American Society of Mechanical Engineers.

parameters be consistent with the basic design conditions. Hence for a given test:

(*a*) The magnitude of the static reaction on the test gear should be the same as that established by the design condition. (A value based upon an "equivalent-mass" analysis may be used where applicable.)

(*b*) The wheel contact velocity for a given free-drop height, as measured at the axle (or bottom of the tire), should be the same as that to be obtained in a hypothetical translational drop from the same drop height.

(*c*) The energy to be absorbed by the test gear, resulting from a drop from a given height, as measured at the axle, should be the same as that part of the airplane's total potential energy that would be absorbed by the test gear in a purely translational drop-test from the same drop-height, effects of interactions of main gear and auxiliary gear being discounted.

(*d*) The direction of the impact load on the gear, relative to the shock-strut axis, should be the same as that established by the particular design condition.

Requirement (*c*), as presented here, is really repetitive since ideally the satisfaction of conditions (*a*) and (*b*) automatically fulfills (*c*).

In addition to the attainment of these basic objectives, the test engineer has a few of his own requirements to meet, the foremost, aside from safety for test personnel, being that he avoid structural damage to the test airplane resulting from dynamic loading at the pivot point.

An analytical evaluation of the degree to which all of these criteria may be satisfied may be made by consideration of the dynamics of the compound pendulum.

Consider the case of the rigid pendulum subjected to constrained rotation, Fig. 1. If the pendulum has its motion arrested suddenly by a stop, the nature of the instantaneous loading at the pivot point is dependent upon the following factors:

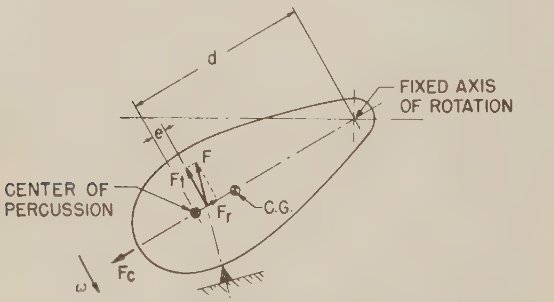
(*a*) The instantaneous value of the angular velocity.

(*b*) The magnitude of the force exerted by the stop.

(*c*) The direction of the stop force relative to the line containing the center of percussion, the center of gravity, and the center of rotation.

(*d*) The displacement of the line of action of the stop force from the center of percussion of the pendulum.

If the line of action of the stop forces passes through the center of percussion, the tangential component produces no reaction at



F = INSTANTANEOUS IMPACT FORCE EXERTED BY STOP
F_t = TANGENTIAL COMPONENT OF F
F_r = RADIAL COMPONENT OF F
F_c = CENTRIFUGAL FORCE
RESULTANT REACTION AT AXIS OF ROTATION, $R = \sqrt{\left(\frac{e}{d}F_t\right)^2 + \left(F_r - F_c\right)^2}$

FIG. 1 "FIXED ROTATIONAL" COMPOUND PENDULUM

the pivot axis. However, the radial component adds algebraically to the simultaneous value of centrifugal force.

If, in the case of a semielastic body, the motion is arrested by a sprung stop, the natural frequency of which is very low compared with the natural axial and flexural frequencies of the body, the behavior of the system is quite comparable with that of the inelastic pendulum.

The rigid-body type of analysis applied to a rotational drop-test setup indicates the nature of the problem of avoiding undesirable loading at a fixed pivot point. Consider a case for tests of main landing gear. If the airplane wheels are dropped on a well-greased horizontal surface, it is generally assumed that the landing reactions act vertically. This being granted, it becomes necessary to orient the pitching attitude of the airplane so that requirement (*d*) noted previously is fulfilled, that is, so that the direction of the shock-strut axis relative to the impact load conforms with the design condition.

This factor precludes the probability of avoiding substantial loads at the fixed-pivot axis even if the test airplane's weight is distributed so that the center of percussion is directly over the line of contact of the main-gear wheels. With the airplane in attitudes intended to simulate either "level-landing" or "three-point-landing" conditions, it is not possible to distribute the required mass so that the line containing the center of percussion and the fixed axis of rotation is normal to the landing reactions.

In the case of the Model PV-1, a 26,500-lb normal-gross weight airplane, calculations for drop tests in three-point attitude, with the center of percussion over the main-gear axles and the tail-gear axle a fixed center of rotation, indicate that allowable impact loads on the main gear could produce a tail-gear drag-load component in excess of 24,000 lb. An estimated value of angular velocity at the instant of peak impact load indicates an additional 3000-lb component, due to centrifugal force, giving instantaneously a magnitude of total drag load on the tail gear greater than that of the airplane gross weight.

In order to avoid the imposition of large dynamic loads at the pivot point, it has sometimes been a practice to provide elastic restraint of the pivot by use of shock cord. This technique may well prevent damage to the airplane structure but still may result in violation of requirements (*b*) and (*c*) relative to contact velocity and energy absorption, depending upon the degree of restraint afforded.

The ideal anchorage for the airplane in rotational drop tests is one whereby the axis of rotation may be placed on a horizontal line through the airplane center of gravity (cg).

The "free rotational" compound pendulum represents a system of this type, Fig. 2. If the pivot axis is allowed to move freely in frictionless horizontal guides that offer complete vertical restraint, no horizontal forces can be applied to the body during its free fall, and the center of gravity will drop vertically. During this period the only force existing at the pendulum support is that required to produce angular acceleration of the body about the instantaneous center of rotation, which falls with a vertical velocity the same as that of the center of gravity. Thus the line containing the instantaneous center of percussion (icp) and the instantaneous center of rotation passes horizontally through the center of gravity. If the instantaneous center of percussion is located directly over the stop, the stop force produces no impact at the moving pivot axis.

EQUILIBRIUM EQUATIONS

Several useful and interesting relationships may be obtained from the equilibrium equations of this system during its free-fall period. By referring to Fig. 2 it may be seen that the position, velocity, and acceleration of the center of gravity (cg) relative to the reference axes are described by

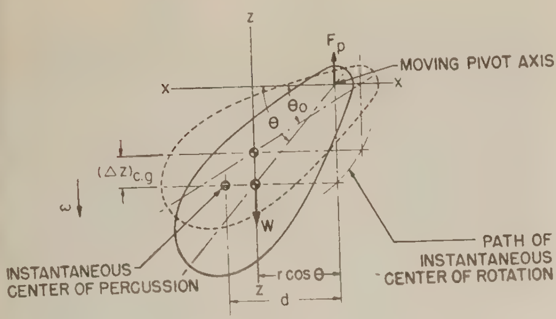


Fig. 2 "Free Rotational" Compound Pendulum

$$(z)_{cg} = r \sin \theta \qquad [1a]$$

$$(v_z)_{cg} = r\omega \cos \theta \qquad [1b]$$

$$(a_z)_{cg} = r\alpha \cos \theta - r\omega^2 \sin \theta \qquad [1c]$$

For translational equilibrium

$$\left(\frac{W}{g}\right)(a_z)_{cg} = W - F_p \qquad [2]$$

For rotational equilibrium

$$\left(\frac{W\rho^2}{g}\right)\alpha = F_p r \cos \theta \qquad [3]$$

From Equations [1c], [2], and [3],

$$(r^2 \cos^2 \theta + \rho^2)\,\alpha - (r^2 \sin \theta \cos \theta)\omega^2 - gr \cos \theta = 0 \qquad [4]$$

Equation [4] may be put in a more convenient form by using $\omega \dfrac{d\omega}{d\theta}$ for α and letting $\omega^2 = 2u$, resulting in

$$\frac{du}{d\theta} - \left(\frac{2r^2 \sin \theta \cos \theta}{r^2 \cos^2 \theta + \rho^2}\right) u = \frac{gr \cos \theta}{r^2 \cos^2 \theta + \rho^2} \qquad [5]$$

Solution of this equation yields

$$\omega = \sqrt{\frac{2\, gr\, (\sin \theta - \sin \theta_0)}{r^2 \cos^2 \theta + \rho^2}} \qquad [6]$$

where θ_0 is the position angle corresponding to $\omega = 0$.

The term, $r(\sin \theta - \sin \theta_0)$ is simply the change in height of the center of gravity, that is, $(\Delta z)_{cg}$.

By use of the concept of the instantaneous center of rotation the relationship between the drop height of the center of gravity and that of the instantaneous center of percussion is apparent

$$(\Delta z)_{cg} = \left(\frac{r \cos \theta}{d}\right)(\Delta z)_{icp} \qquad [7]$$

From basic mechanics $d = \dfrac{k^2}{r}$, where k is the radius of gyration about the axis of rotation, and r is the distance from the center of rotation to the center of gravity.

Here $d = \dfrac{r^2 \cos^2 \theta + \rho^2}{r \cos \theta}$, so that the vertical velocity of the center of percussion in terms of its drop height is

$$(v_z)_{icp} = d\omega$$

$$= d\sqrt{\frac{2g\,(\Delta z)_{icp}\, r \cos \theta}{(r^2 \cos^2 \theta + \rho^2)\, d}}$$

$$= \sqrt{2g\,(\Delta z)_{icp}} \qquad [8]$$

Since the vertical velocity attained by the instantaneous center of percussion in falling from a given drop height is the same as that attained by a body falling freely from the same height

$$(a_z)_{icp} = g$$

and, from Equation [2] and the counterpart to Equation [7]

$$F_p = W\left[1 - \frac{(a_z)_{cg}}{g}\right]$$

$$= W\left(1 - \frac{r \cos \theta}{d}\right) \qquad [9]$$

If the system is prevented from rotating by an external restraint acting along a vertical line through the instantaneous center of percussion, the static reaction at the pivot axis is

$$R_p = W\left(\frac{d - r \cos \theta}{d}\right)$$

$$= F_p \text{ for the same values of } \theta$$

Free Rotational Compound Pendulum System

The "free rotational" compound pendulum system ideally permits fulfillment of all of the basic rotational drop-test requirements for main gear if it is physically feasible to satisfy the following conditions:

1 The inclination of the shock strut relative to the impact load (assumed acting vertically) may be made to conform with the design condition.

2 With the airplane in the attitude consistent with item 1, a distribution of weight may be made such that, for the entire loaded airplane, (*a*) simultaneous values of $r \cos \theta$ and ρ satisfy a value of d predetermined from a choice of moving-pivot location; and (*b*) simultaneous values of $r \cos \theta$ and W satisfy the requirement for test-gear static reactions.

It is to be noted that the test-airplane gross weight and center-of-gravity position, as such, need not conform with those of the design condition; nor need the disposition of weights in the fuselage be based upon the actual distribution of fixed equipment or useful load. It is, of course, important to avoid local overloading of any part of the structure; the probability of this occurrence may readily be determined by analysis of the weight distribution with regard to anticipated local accelerations.

In practice, deviations from the theoretical performance exist; these may be summarized qualitatively as follows:

(*a*) *Eccentricity and Nonverticality of Impact Load.* Because of the inclination of the shock strut the fore-and-aft position of the axle relative to the airplane varies as the strut is compressed under load. Thus at only one position may the test-airplane instantaneous center of percussion be directly over the axle. The effect is usually very small, however, the maximum eccentricity from this source being of the order of 1 per cent of the value of d. Another contribution to eccentricity may result from change in effective mass. Prior to impact, the airplane may be considered as a relatively rigid body; after impact the semisprung mass of tire, wheel, axle, and piston behaves altogether differently from the rest of the airplane. Here, again, the magnitude of these effects is generally small since the percentage change in "rigid" mass is small.

Potentially of more importance than the horizontal eccentricity of axle relative to the instantaneous center of percussion is the drag-load component resulting from forward or aft motion of the tire on the impact surface. Even with a liberally greased contact surface it is not inconceivable that the direction of resultant load may vary by several degrees from the vertical, depend-

ing upon the coefficient of friction and the moment of inertia of the wheel-and-tire mass. This factor is of little practical consequence in so far as the magnitude of dynamic loading at the pivot axis is concerned; it is more significant that the nature of the effect is generally such as to be additive to the design drag-load component, simulation of which is intended by prior inclination of the shock-strut axis. More will be said about these effects in the discussion of the test results.

(*b*) *Nonrigidity of Airframe.* Potentially, a major reason for differences between the idealized and the actual behavior might appear to lie in the fact that the airplane is not a rigid body. Quantitatively, an analysis of the effects of elasticity is a formidable task (1, 2).[3] Moreover, it would appear to be a misdirection of effort to attempt such an analysis merely for purposes of of drop-testing

Qualitatively, it may be noted that the load-time history of a landing event is usually very long in comparison with the natural period of vibration of any of the significant weight items. Hence pure resonant effects may be discounted. However, both the release shock and the landing shock excite in the airplane components transient oscillations which may have a measurable effect, not merely at the pivot axis, but also on the test-gear dynamic loading. It might be expected that elastic effects would be most noticeable for critical metering pin-and-orifice combinations. Cases are known wherein a particular metering pin, prescribed as a result of landing-gear tests in a translational drop-test rig, was found not to give optimum performance in airplane drop tests. However, it should be noted that differences in overall test techniques, including setup parameters and instrumentation, may well produce differences of comparable magnitude.

(Thrust line was inclined 18 deg, nose down, and tail gear was swiveled 180 deg to avoid interference between fork and guide block.)

2 APPLICATION TO LOCKHEED PV PATROL BOMBER DROP-TESTS

Basic Test Arrangement

The moving tail-pivot test arrangement has been used in drop-tests of the main landing gear of PV patrol bombers. These tests were conducted for both "level-landing" and "three-point landing" conditions to determine energy-absorption and load-factor data throughout a range of drop heights.

As a matter of convenience, the tail-gear axle was chosen as the moving-pivot axis. The tail-gear strut was locked in a fully compressed position by steel straps attached to the torque-knee lugs. The tail wheel, less tire, was set on a steel track laid in the base of a horizontally slotted guide block, which was shimmed up from the floor to the height required to give the specified inclination of shock-strut axes for each landing condition. The installation is shown in Fig. 3.

The weight of the test airplane, consisting primarily of basic structure less outer wing panels, constituted about 20 per cent of the normal gross weight just prior to the start of the test setup. At this time it was desired to add the required mass in such a manner that the proper static reactions were obtained and that the center of percussion of the entire test airplane was placed over the line of contact of both main-gear wheels. From basic weight data the weight, location of the center of gravity, and pitching radius of gyration about the center of gravity were calculated for the empty test airplane. Weight and center-of-gravity location were checked by actual weighing.

As additional weights were placed in the airplane, a running tabulation of the weight-distribution parameters was made until, by successive approximations, the calculations indicated that the desired conditions had been satisfied. For overload conditions weights were added in equal increments both forward and

aft of the center of gravity at distances equal to the computed radius of gyration about the center of gravity for the normal-

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

gross-weight condition. In this manner the location of the center of percussion was held constant, and the increases in main-gear static reactions were made proportional to the corresponding increases in gross weight of the test airplane.

In the loading of the test airplane no particular effort was made to obtain exact correspondence of fuselage load distribution with the actual airplane weight distribution, although provisions for large items of fixed equipment or useful load greatly influenced the operations. It was considered important, however, to reproduce power-plant weights and centers of gravity locations inasmuch as each engine-mount support structure was closely associated with the landing-gear supporting structure. As a matter of economy the wing outer panels were not installed, having been damaged in previously conducted static tests. However, it is considered that the over-all behavior of the landing gear and wing center section would have been somewhat more representative had it been feasible to effect a normal distribution of wing weight. Moreover, it would undoubtedly have been more rational from the standpoint of wing torsional moments to have reduced "power-plant" dead weight by the ratio of the distance from the instantaneous center of rotation to the instantaneous center of percussion and the distance from the instantaneous center of rotation to the power-plant center of gravity. Yet in all probability such a reduction would have involved overloading the fuselage forebody in the three-point-landing condition because of the necessity of having enough weight forward to locate the instantaneous center of percussion properly.

Drop-Test Instrumentation

Several months prior to the start of the tests it was recognized that a considerable amount of data would need to be taken in as short a period of time as possible because of the pressure of other testing schedules. Accordingly, special instrumentation was devised to permit rapid recording and reduction of the data.

In the PV-1 tests simultaneous and continuous recording was made of the following quantities as a function of time:

1 Load on bottom of tire.
2 Tire deflection.
3 Shock-strut piston travel.
4 Airplane travel from the instant of release.

These measurements were made concurrently on both left-hand and right-hand gear. In addition, the following quantities were recorded on one side only:

5 Landing-gear drag-strut load.
6 Longitudinal deflection of the lower end of the shock-strut outer cylinder relative to the plane of the wing main beam.

In tests of the PV-2 facilities were available for measurements of side-strut and drag-strut axial loads on both sides, as well as tail-pivot loads.

All "load" measurements were made by means of SR-4 strain gages installed on structural members and incorporated in 1000 cycle-per-sec alternating-current bridge circuits, the output voltages of which were amplified, rectified, and impressed on the galvanometer elements in a recording oscillograph. Tire and strut deflections, as well as airplane travel, were recorded in a basically similar manner through the use of specially constructed slide-wire potentiometers. The outer-cylinder deflections were detected by a bending-beam-type of strain-gage pickup.

The measurement of axial loads in tubular struts posed no new problems, since the techniques of dynamic strain measurement and associated calibrations to obtain corresponding loads are fairly well established. However, the determination of dynamic loads on the shock strut required a somewhat different approach, inasmuch as there were no locations on the gear itself where anticipated strains sufficiently large for accurate measurement could be considered as absolutely indicative of load on the member. Accordingly, it was decided to drop the wheels on platforms, each of which was supported by three tubular pedestals to which strain gages were attached. By virtue of identical load-strain sensitivities of the pedestals and of the manner of incorporating the gages in the bridge circuit, the load indication of each platform was made independent of the load center relative to the three supports and also of any local pedestal bending strains that might be developed from horizontal-load components.

A typical oscillogram is shown in Fig. 5. It is to be noted that traces labeled "inboard" and "outboard" deflections of each tire appear. It was found necessary to use two slide-wire potentiometers on each wheel because of cumulative rotation due to bending of wing center section, shock strut, and axle. Thus a means of knowing true deflections at the tire center line was afforded, as well as the magnitude of the rotation. Each oscillogram trace has its own calibration factor in terms of its physical counterpart, the calibration being facilitated by the static conditions prior to release of the airplane and immediately after the airplane came to rest.

Test-Data Interpretation

In the interpretation of the oscillograms it was necessary to correct the platform-load indications for the effects of semisprung mass of wheel and axle, in order to obtain magnitudes of load experienced by the shock-strut outer cylinder and supporting structure. In general, the peak loads on the tire occurred at a time when the shock-strut stroke-time trace indicated very little differential acceleration of sprung and semisprung airplane masses. Accordingly, the peak loads on the outer cylinder were obtainable quite accurately merely by taking the appropriate fraction of the platform-load indication. As a matter of convenience, this same fraction was usually applied to all values of platform load in the process of constructing load-stroke and load-mass travel graphs from the oscillograms. Inasmuch as the semisprung gear weight amounted to only a few per cent of the static platform reaction, the error involved was usually of no practical consequence.

The recording of dynamic loads and deflections on both main gears made possible a determination of over-all energy relationships. By comparing the potential energy of the airplane prior to release with the energy absorbed in both main-strut and tire units up to the time of minimum center-of-gravity height, an estimate of the minimum amount of energy absorbed by the airframe could be made. The term "minimum" is used, since the nominal center-of-gravity travel was used in computations, without regard to the incremental energy accruing from structural deformation.

In the earlier series of tests, analysis of the oscillograms showed that peak drag-strut loads were considerably greater than were anticipated. This condition was true for both three-point-landing and level-landing tests. Two readily apparent reasons for the differences were (*a*) that the peak load on the gear was developed earlier in the stroke than had been the case in previously conducted jig drop tests and (*b*) that the effects of structural deformation had not been included in the preliminary stress analysis. However, even with allowances for these factors, the drag-strut loads appeared to be too large. Qualitatively, the residual discrepancy was attributed to nonverticality of impact load due to inertial or frictional effects.

The PV-2 test instrumentation permitted an indirect evaluation of the degree of main-gear load eccentricity relative to the center of percussion. With the airplane in a "tail-high" attitude intended to simulate "level landing with inclined reactions," the line of action of the hoisting gear very nearly intersected the line

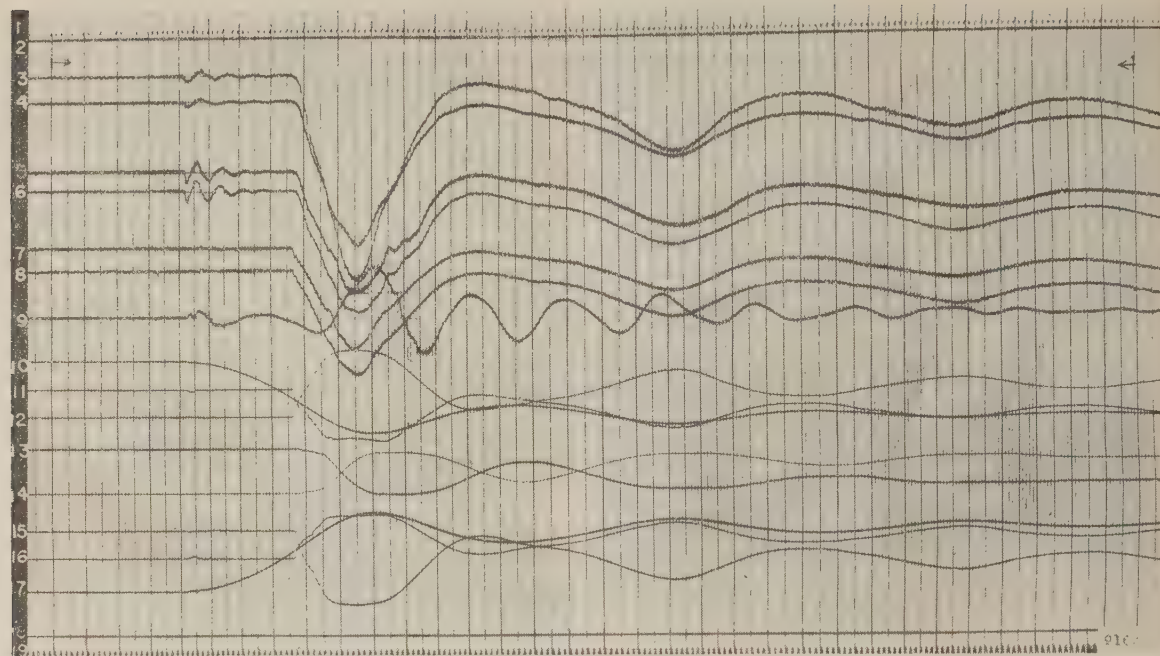

Fig. 5 Typical Oscillogram, With Numbered Traces Corresponding to Physical Quantities

(1 and 19, sixty-cycle timing waves; 2 and 18, reference line; 3, left drag-strut load; 4, right drag-strut load; 5, left side-strut load; 6, right side-strut load; 7, left-platform load; 8, right-platform load; 9, tail-gear load; 10, left-wing travel; 11, left tire, outboard deflection; 12, left tire, inboard deflection; 13, left strut stroke; 14, right strut stroke; 15, right tire, inboard deflection; 16, right tire, outboard deflection; 17, right-wing travel.)

of contact of main-landing-gear tires. Hence if the airplane behaved as a rigid body, and if the impact force acted vertically through the center of percussion, no change should have been expected in the tail-gear static reaction other than that occasioned by a slight change in airplane attitude.[3] Actually, a rather significant change in tail-gear reaction occurred, as can be seen by reference to the oscillograph trace in Fig. 5. Statically, prior to release, the bottom track of the horizontal guide applied an upward force on the tail wheel. Shortly after the instant of initial main-gear impact this force diminished to zero, remaining at zero for an instant while the tail wheel traveled freely about 1/16 in. before encountering the restraint of the upper guide. The peak downward load on the tail gear was attained shortly after the peak loads had been reached on the main gear. This behavior was typical for this series of tests, the magnitude of dynamic tail load increasing with main-gear drop height, and the time of maximum occurring at or shortly after maxima on the main gear. The persistence of tail-load oscillations after the main landing event was also characteristic.

An obvious deduction to be made from the tail-pivot loading is that substantial drag forces were developed as the semisprung gear elements moved forward due to compression of the inclined shock struts. Thus the diving moment induced by these drag forces was balanced by a downward dynamic load on the tail pivot. The validity of this conclusion is strengthened by the fact that the recorded peak loads on the landing-gear drag struts are in good agreement with values calculated by means of the instantaneous attitude of the airplane, the measured vertical loads on the gear, and values of drag load required to balance the simultaneous tail-pivot load. The data indicate that at the instant of peak vertical load the unwanted drag load may have been larger than 12 per cent of the vertical load. Thus the direction of impact load relative to the shock-strut axis was considerably more severe than that prescribed by the design condition.

[3] Reference to Equation [9], et seq.

Drop-tests for simulation of "three-point landing with vertical reactions" produced effects in the opposite direction, that is, the aft acceleration of wheel-and-tire masses demanded by the compression of the shock struts led to the development of peak resultant loads acting somewhat forward of vertically upward. Again, the net effects on the gear and its supporting structure were more severe than were intended.

Conclusions

The author feels that there are two definite conclusions to be drawn from the experiences accumulated both during the drop-test programs discussed herein and during more recently completed rotational-jig drop tests employing the same principles:

1 Drag-load errors arising from wheel inertia or from friction between tires and impact surfaces are not necessarily negligible in any type of drop-testing, whether simulation of the proper drag component is sought either by inclining the shock-strut axis or by inclining the contact surface. It is significant that, in general, the former expedient produces effects in a direction to aggravate loads in the drag-resisting structure, whereas the latter tends to alleviate them, resulting in an unconservative test unless deliberate compensation is afforded. While the control of these factors may be unduly costly, the measurement of their effects on the airplane structure appear to be justified as a standard procedure. The degree of refinement to be attained in instrumentation and in adjustment of test setup parameters is indicated by an over-all view of the problem. Drop-testing to simulate a particular "instantaneous" design condition is one thing; drop-testing to simulate actual critical landing conditions is quite another.

2 The "free-rotational" drop-test method described herein is believed to be an improvement over previously used rotational test methods. Moreover, from the standpoints of safety, accuracy, and ease of airplane control, it appears to offer advantages over translational airplane drop-testing in cases where simulation of dynamic landing loads on the entire airplane structure is not intended.

Acknowledgment

Acknowledgement is due a number of Lockheed engineers for their contributions, especially toward the initial work in 1943. Particular note should be made of the assistance given by G. E. Nichols and W. Bush in the testing and data reduction; of the helpful suggestions made by J. S. Edison, P. C. Mortenson, and R. Contini; of the development of the initial electrical instrumentation by R. E. Rawlins; of the guidance by V. S. Upton under whose direct supervision the work was carried out; and of the basic contributions by W. C. Hurty, whose interest and encouragement made possible the evolution of the new techniques described herein.

Some Suggested Specifications for Thermal Ice-Prevention System for Aircraft

By L. A. RODERT,[1] INDIANAPOLIS, IND.

The general conclusions from research and development of the airplane thermal ice-prevention system are given and additional comments in discussion of present knowledge are made. Details of design are discussed whereby some faults of early applications of the thermal system may be avoided. Specifications for the thermal system are given as an aid to operators and others desiring to provide the most effective protection against the formation of ice on airplanes to be designed for commercial or military use.

Introduction

THE need for closer adherence to scheduled operations becomes increasingly urgent as the military and commercial use of the airplane is extended. Attention therefore is being given to the improvement of equipment and operational methods which will enable the airplane operator to achieve the regularity which is necessary to meet the demands of the public and competition.

The airplane is handicapped during inclement weather by obstructions to visibility and the formation of ice. The maintenance of schedules also is affected at some terminals by congestion of air traffic. While visibility and traffic problems may be solved by signal devices and operating procedures, the ice problem requires an intimate consideration of the airplane.

Research and development activities in many countries have been directed in search of a solution to the ice problem. These activities have, in general, concluded that the problem can be solved by the use of heat. Although it is fortunate that an answer has been found, heat is not entirely a fortunate solution because the internal parts of the airplane are adversely affected and complicated by its application. Engineering skills which can cope with the problems of flight and the internal mechanism therefore have to be directed to the task of applying the thermal system.

The locale, intensity, and distribution of heat and the mechanical, electrical, and aerodynamical details must be considered when the airplane ice-prevention specifications are prepared. The reports of the researchers have been limited in many instances to a discussion of the practicability and thermal requirements of the system, and rightly so, since these were the objectives. During the conduct of the tests, which involved the operation of several airplanes in natural icing conditions, practical design and operational information was also obtained. In the present paper, the practical considerations of design will be considered on a more equal plane with the theoretical objectives of the researches. It is hoped that this treatment of the knowledge will be helpful during the interim between the present and the later date when the manufacturers and operators will have had adequate experience with applied aircraft to establish the needed empiricisms.

Ice-Prevention Data

After the preliminary exploration in the United States and Germany, from which the practicability of the thermal system of ice prevention was established, many projects were undertaken in order to test the application to various parts of the airplane and to determine the intensity, distribution, and extent to which heating must be applied in order that ice might be alleviated. In this country, the application to all vulnerable parts of the aircraft has been recommended (1, 2, 3, 4, 5, 6, 7);[2] in Canada, the National Research Council has advanced and endorsed the use of heat on the propeller; and in Germany, the thermal system has been applied to lifting surfaces and windshields (8, 9). British researchers, collaborating with and actively participating in the work in this country (due to the difficulties imposed by hostilities over the British Isles), have also approved the thermal system as superior to other methods for all vulnerable parts of the airplane. These results all pertain to aircraft of conventional configuration, size, power loading, and power-plant installation.

Aerodynamic Lifting Surfaces. When heat is delivered to the leading edge 10 per cent region in sufficient quantity to raise the average leading-edge skin temperature 100 deg F above the ambient air temperature, while flying in dry air at 18,000 ft pressure altitude and at 60 per cent rated engine power, adequate heat is provided to prevent or remove ice formations from wings and empennage surfaces. This conclusion has been reached from tests with full-scale aircraft in flight in natural icing conditions. Conclusions based upon the data are considered to be applicable to conventional airfoils of from 4 to 20 ft chord whose pressure distribution is similar to that of the N.A.C.A. 230 airfoil series and whose thickness is from 6 to 18 per cent of the chord. The surfaces of the wings were normally clean but not aerodynamically smooth. The condition of the surfaces was more likely to be hydrophilic than the hydrophobic. The data were established from flights in several aircraft over a period of 5 years' time, over a wide geographical area, in various types of meteorological conditions, and with different observers (1, 2, 3, 5). Encounters with what may be called severe icing conditions have been successfully experienced.

The chordwise heating intensity over the leading edge 10 per cent chord region gave a temperature rise which was uniform within about 15 deg F in one airplane which had satisfactory protection in all conditions.

Ice does not form in the vicinity of the controls or control hinges unless, by peculiar rigging, a part of the control surface is made to protrude beyond the normal boundary layer of air which passes over the wing. Hinges, balances, or other protuberances which may occur from faulty manufacturing techniques will collect ice when the leading edge is heated sufficiently to keep ice off from the stationary part of the airfoil. When ice is allowed to refreeze on the regions rearward from the leading edge by reducing the heat below specified values, the formations have always occurred forward of the control-hinge regions.

Flight in clouds containing unusually large quantities of water at air temperatures below 32 F caused the wing leading edge to be

Presented at the Aviation Division Meeting, Los Angeles, Calif., June 3–5, 1946, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

substantially wetted back to the 5 to 7 per cent chord point on the upper surface. Observations were not made directly on the lower surface, however, the wetted area is thought to be about the same as on the upper side. The area rearward from the 5 to 7 per cent chord region has been observed to be only partially wetted. No ice formed on areas rearward from about the chord point of maximum ordinate on wings of large chord, and, from this observation, it is concluded that no water is in contact with the skin in this region since the temperature of the skin was below the freezing point of water. This conclusion is not thought to be valid for airfoils of 4 ft chord or less.

In flights through cumulo-nimbus clouds of major development, large quantities of water in the form of snow, sleet, and rain, held aloft by strong up-currents have been encountered which caused the deposit of a slushlike formation along the stagnation-pressure region for short periods of time. These formations were as much as 2 in. wide and $^1/_2$ in. thick in some cases of extreme severity.

The delivery of heat to the aerodynamic lifting surfaces has been accomplished by the following means:

1 Exhaust tube within the wing leading edge (1).

2 Circulation of heated air within the leading edge and discharged from the airfoil interior in the vicinity of the trailing edge or control-surface hinge line (5).

3 Circulation of heated air within the leading edge and discharged from the airfoil interior into the boundary air near but to the rear of the transition point on the low-pressure side, high-pressure side, or both (2, 3).

The exhaust tube within the wing was discarded in favor of the air-circulating systems because the latter has been found to be more easily constructed and maintained and to be more readily employed on most airplanes.

Attempts to deliver heat to the wing leading edge by the spanwise flow of heated air along the wing leading edge have not been successful. All successful leading-edge designs have been adaptations of the Junkers leading heat-intercooler design (8) which employs a spanwise plenum, chordwise flow for heat exchange, and either a chordwise or spanwise flow for the outgoing air.

The wing-heating systems have been made without serious deleterious effects on the strength, construction, weight, or maintenance of the aerodynamic surfaces.

Windshield. The vision of the pilot and copilot of airplanes at speeds under 200 mph, indicated, has been maintained during flights in icing conditions by the transmission of about 1000 Btu per sq ft per hr through the outer surface of the windshield glass (2, 4). The prevention of ice on the windshield has also been accomplished on one airplane by the passage of a layer of heated air over the exterior from a slot at the forward edge (5). About 10,000 Btu per sq ft per hr was employed in the externally discharged air-heating system. However, the mechanical design was inferior, and it is believed that less heat would be required in a better arrangement.

Greater amounts of heat than that just indicated have resulted in excessive warmth in the pilot's cabin particularly in airplanes in which the pilot's face is near to the windshield. Heating the windshield to a limited degree increases the resistance of the glass to the impact of bird strikes according to tests conducted by the Civil Aeronautics Authority. Heating the windshield to a temperature above 140 F seriously weakens the glass and has a deleterious optical effect upon the plastic binder of safety glass.

Heat has been transmitted in the necessary quantities by the following:

1 Circulation of heated air between the panels of a double-glazed windshield.

2 Electric power through the use of embedded heating wires in the glass.

3 Circulation of heated air over the exterior surface.

4 Electric power through the use of external heating wires.

5 Electric power through the use of transparent conducting surfaces.

It is very important to remember that vision through the windshield is the important objective in windshield ice prevention.

The solution to this very important part of the ice problem must consider ice prevention on the outside, frost removal on the inside, resistance of the panel to the impact of flying birds, and the other more obvious construction and service requirements. Hope has long been held that a transparent and durable electrical conducting film for the coating of glass could be discovered whereby the windshield panels could be heated with electric power. Such a product has been discovered and developed by the engineers of the Pittsburgh Plate Glass Company. This discovery, which has been given the name of "Nesa," promises to solve the windshield icing problem in an optimum manner for all the factors involved wherever electric power is available in the required quantities.

The improvement of the optical qualities of the doubly glazed windshield has been attempted by the treatment of the glass surfaces for the reduction of the surface reflectivity. Coating the glass surfaces with magnesium fluoride by the evaporative process was not successful in one attempt. The use of the doubly glazed windshield has several disadvantages. Tests have shown the increased reflectivity of the greater number of surfaces to be detrimental to the pilot's vision, particularly at night in the landing maneuver. Water precipitates form on the inner side of the outer glass occasionally on some installations during taxi and take-off runs due to the circulation of high-humidity air past the cold outer panel. The fogging clears soon after the ducts are cleared of the moist air and the temperature of the air rises. The collection of foreign particles on the interior surfaces of the glass necessitates frequent clearing in dusty regions.

Propeller Blades. Ice can be removed or prevented from forming on propeller blades by the provision of heat to the blade leading-edge region or to the entire blade section. The application of the thermal system to the propeller blade has been accomplished by the use of electric power and by passing heated air through the interior of blades having an open passage from root to tip. The minimum quantity of heat required for a propeller blade has not been reliably established; however, sufficient data have been obtained whereby practical and reliable propeller protection can be achieved for blades currently in use. The results indicate that blades for a 12-ft-diam propeller will require from 1000 to 1200 watts of electric power per blade when turning at about 1100 rpm propeller speed and flying at about 180 mph indicated airplane speed (6). Other results indicate that blades of a 15-ft-diam propeller under about the same operating conditions require from 1000 to 1500 watts of electric power per blade (10).

Flight tests in natural and simulated icing conditions by independent researchers have shown that the thermal system for propellers may be operated intermittently with satisfactory protection for the propeller and with a great saving in electric power. When operated intermittently, the power is applied to a propeller for a short time during which the ice is removed and then the heating is interrupted. During the interruption, heating is applied to another propeller on which a small amount of ice has been permitted to form. Intermittent operation is thought to require a slight increase in blade heating in order to minimize the time required for ice removal and reduce the size of ice particles thrown off.

The electric heating of propeller blades has been accomplished by neoprene blade shoes in which an electric resistance of either conducting rubber or wire was constructed. The blade shoes have been about 60 inches long in some successful installations. Some blade shoes have given several hundred hours' service in varied conditions without excessive abrasion while others were severely damaged by one flight in snow and heavy rain.

The shoes were applied to the blade by adhesives. The attachment changed the contour of the blade profiles from 0.050 to 0.065 in. at the leading edge and about 0.010 in. at the 20 per cent chord point. The blade shoes covered about 25 per cent of the blade chord on the camber face and slightly less than 20 per cent on the thrust face on one installation which gave favorable results. The heating intensity of the electrically heated shoes was twice as great over the leading-edge part of the shoe as over the areas immediately to the rear of the leading edge on camber and thrust faces (6).

Power has been successfully supplied to the electrically heated blades by propeller-hub-type alternating-cuttent generators and through slip ring and brushes from an electric power source, such as the regularly installed generator.

Air for use in the air-heated hollow steel propellers was supplied from heat exchangers in one successful demonstration of the system. The energy employed in the propeller air-heated system was excessive and all ice was not prevented in every test, although it should be noted that by baffling the blade interior the heat would have been better employed and better protection would have been provided.

Miscellaneous Parts. Although the results of tests on wings, windshield, and propellers are indicative of how ice may be prevented on other vulnerable parts of the airplane, direct solutions to the miscellaneous problems have not been established. Individually, the collection of ice at points on the airplane other than on the wings, windshield, or propeller may not seriously affect the operation of the craft. Collectively, however, the miscellaneous problems, unless solved in part, may so handicap the airplane that the advantages of the improved protection to the wings, etc., will not reward the operator with the improvement in reliability which would otherwise be achieved.

The formation of ice on exposed frontal parts of the airplane such as the fuselage, engine cowls, and propeller spinner has been observed to be of sufficient size and shape to reduce the performance slightly, create a hazard when the formations become dislodged and fly rearward, and in the case of the cowls create an interference with the propeller blades which might interfere with blade-angle movement in an extreme case.

The formation of ice on radio antenna wires has broken the wires on most airplanes which have been operated in severe icing conditions unless steel cables were used in place of the copper wire which is customarily employed. Ice formations on radio antenna insulators have caused a reduction in the distance over which radio signals could be transmitted.

The formation of ice on the mast to which the static-pressure orifice for the airspeed and altimeter system is mounted causes an error in the meter readings and increases the drag of the airplane. In extreme cases the masts have been broken away from the airplane fuselage.

The formation of ice inside and on the edge of inlets to air ducts will reduce the inlet area and increase the air-pressure losses in the duct. Turning vanes in air scoops will collect ice and cease to be an advantage to the circulation of air. When ice dislodges from the opening and passes into the duct, due to flight into warmer air temperatures, the formations have seriously stopped the flow of air into a duct for a period until the ice has completely melted.

The formation of ice on exposed moving mechanisms has rendered such equipment inoperative. The exposed cable and pulley wheel or similar devices on propeller governors which are mounted on the front face of the engine, and the alternate air-intake door and operating arms for carburetor air intakes are examples of equipment which has been affected by ice formations. Slight accretions have been observed on control-surface hinges and balance weights but not of sufficient size to cause interference since these parts are ordinarily shielded by the forward part of the aerodynamic surface.

Engine Air-Induction System. The established practices of heating the engine air in this country and of heating the parts of the carburetor and induction system walls in the United Kingdom will prevent and remove the formations of ice in the engine air-induction system (7). Most airplane service installations of the air-heating system are unsatisfactory because of high maintenance requirements and the use of unsatisfactory mechanical arrangements for adjusting the carburetor air temperature. The air-temperature rise which is required for the removal or prevention of ice in the induction system is known by most airline and military operators and will not be discussed here.

Equipment

The application of the thermal ice-prevention system has necessitated the invention and development of new and unique mechanisms. The success of the detail design of the system is dependent upon the judicious choice and use of these devices. In the conduct of full-scale research, some experience was gained on some of the mechanical, thermal, and electrical equipment which must be used to implement the thermal system. These data are not a substitute for long service experience but may be helpful in the current phase of the development.

Sources of Heat. Heated air has been provided for wings, empennage, windshield, and propeller by exhaust gas-to-air heat exchangers in service and experimental airplanes, and by combustion heaters in experimental airplanes in this country. In Germany, the heat exchanger, combustion heater, and a mixture of exhaust gas and air have been employed as heat sources. Adequate heat capacity can be achieved with any of these types of heat source although several airplane systems have been designed which failed to meet the design requirements in this regard. Heat exchangers have been employed in service in large numbers which have given no cause for maintenance after thousands of hours flight time. Other heat exchangers have not given satisfactory service and have been replaced. Combustion heaters have been employed in service in sufficient volume and for a long enough time (for cabin-heating purpose) to indicate that this type of source can be made satisfactory. Minor service complaints have been experienced but none has been found which involves unsolvable problems.

Installations of the exhaust-gas exchanger have been made which provide adequate heating under all necessary operating conditions (11). Whereas the use of the combustion heater obviously involves an economic loss due to the use of gasoline for heat, the continuous passage of air and exhaust gas through the heat exchanger also involves a power loss which must be compensated for in increased power of the engines in order to maintain unaltered climb and speed performance (12).

Electric power has been provided by propeller-hub-type alternating-current generators for propeller ice prevention and the airplane's electric system. Service difficulties have been experienced in the use of the hub generators; however, the problems do not appear beyond solution.

Air-Distribution System

The distribution of air from the heat sources to the heated areas has been accomplished with aluminum, aluminum strength

alloys, mild steel, stainless steel, and glass-fabric tubes. The difficulties experienced with the duct systems were as follows:

1 Excessive air-pressure loss due to small size ducts, circuitous paths, internal protuberances, collapsed fabric flexible connectors, sharp corners, and improperly located or shaped guide vanes.

2 Excessive maintenance due to use of soft metals which were easily dented, use of thin metal which fluttered and failed in fatigue, duct connections which made repair of any part very difficult, use of insulation materials which deteriorated under vibration and wear, and control valves which failed elastically or in fatigue due to the use of small metal gages.

3 Off-gassing of pungent volatile materials when hot.

4 Creation of a fire hazard by the absorption of inflammable liquids in duct-insulating materials.

5 Air losses at duct joints and seams.

Controls. An electric control consisting of motor-actuated air valves, overheat turn-off switches, off-on signal lamps, on-off switches and a signal test circuit has been found satisfactory in one experimental system which employed heat exchangers (5). So-called safety devices and alarms failed more frequently than did the equipment against which failure the safety device was to provide.

Instrumentation. The definition of the properties of a thermal ice-prevention system has been accomplished with great difficulty. The use of the very elaborate and expensive measuring equipment and testing methods has not altered this situation (5). The measurement of pressures is handicapped by the turbulent condition usually existing in the duct system. The measurement of pressures is difficult because the instrument usually altered the condition being measured. With care, air flow rates can be measured to within plus or minus 10 per cent. Attempts to invent and develop ice-rate indicators have not resulted in success.

Temperatures can be measured with accuracies as given in Table 1.

TABLE 1 PROBABLE ACCURACY OF TEMPERATURE MEASUREMENT IN FLIGHT

Item	Range, deg F	Accuracy, deg F
Metal structure	0 to 300	±8
Metal structure	300 and above	±20
Ambiant air	—20 to +40	±1[a]
Duct air	0 to 300	±10
Leading-edge skin	0 to 200	±10
Engine exhaust gas	1000 to 1800	±25

[a] With greatest care and with correction for kinetic effect on a wetted thermometer bulb in a moving stream.

The stresses induced in a heated wing have been measured in tests from which apparently reliable results were obtained. The accuracy of this work is stated to be ±400 psi for the stress-change data involved in the heated wing (13).

The measurement of the temperature of the ambient air has been studied with care for the case of the thermometer bulb being located in a moist moving stream (14).

Meteorology

The measurement of the meteorological factors, i.e., water content, droplet size, and air temperature, has been undertaken by several capable engineers and the work continues, but the results thus far have not been encouraging. The best information on water content now available is that measured at mountain top weather bureau stations and that resulting from analytic studies which are based upon fundamental concepts of the physics of the air. Limited flight data substantiate data collected by ground stations and from analytical studies. The data are more satisfactory for stratus-cloud structures than for frontal or vertical developments. The great variations within clouds of vertical development and frontal phenomena make the measurement in these conditions particularly difficult.

The water content and droplet size in stratus clouds have been estimated to approach the values given in Table 2.

TABLE 2 ESTIMATED PHYSICAL DATA ON WATER IN ATMOSPHERE

Air temperature, deg F	Droplet size, $\mu\left(\frac{1}{1000}\text{ mm}\right)$	Water content, g per cu m
0	10	0.50
5	13	0.55
10	16	0.75
15	19	1.15
20	23	1.65
25	26	2.30
30	29	2.85
32	30	3.00

The values given in Table 2 are established by a faired line which has been drawn on a graphical presentation of weather-bureau data (15). The faired curve was drawn so as to give values which in all cases exceeded the data thus far observed and therefore is probably conservative. Our knowledge of the weather is obviously inadequate.

Operational Factors

Flight tests have been made by various observers over the United States from the Pacific Coast to the Great Lakes region, and over Canada from the Lakes to the Atlantic Coast and beyond. No variation in the nature of ice due to geography alone should be expected and none has been observed. Most severe and frequent icing conditions have been observed where a combination of large water content and subfreezing temperatures are encountered. The movement of Pacific air masses over the mountains along the Pacific Coast and the movement of frontal disturbances from the central mid-continent in an easterly and northerly direction cause severe icing conditions. Air mass or local weather does not usually produce dangerous icing conditions except over terminals where traffic is held aloft for long periods at fixed altitudes.

As has been reported by many investigators, formations can occur at air temperatures from 32 F to as low as —40 F or lower. Flight tests have been made in which icing has been encountered up to 18,000 ft pressure altitude. Reports have been recorded from flight operations over the North Atlantic of icing conditions which extend to about 27,000 ft pressure altitude. Icing at altitudes above 20,000 ft is found only in clouds of vertical development and therefore occurs over limited areas or along narrow lines.

Changing the velocity of an airplane will affect the formations of ice in accordance with the kinetic equation (14). Present transport aircraft do not fly sufficiently fast to prevent ice on the wing except at air temperatures near 32 F. The velocity of the outer blade radius sections of the propeller, however, is heated by the kinetic effect to a degree which will prevent the formation of ice under most conditions. In order to take advantage of the velocity effect in the design of propeller ice-prevention equipment, it is necessary to consider the thermal conductivity and other factors involved in the blade-heating problem (16).

The tests in icing conditions have involved sustained flight for over 2 hr in intermittent, moderate, and light icing conditions. Tests in severe conditions have been for short periods only because of the limited size of the regions in which such conditions have been found. Several experiences with severe conditions have been encountered for periods of about 20 min.

The performance of a system cannot be judged by an observation at any one instant because some ice accretions on the surface of an airplane wing which is heated less than that required for complete prevention will accumulate and intermittently be blown away, the bond having been broken by heating which was not adequate for complete prevention.

Operations have been made in icing conditions during engine warm-up, taxi, take-off, climb, cruise, let-down, landing, single engine cruise, and single engine[3] let-down with adequate protection provided. Frost has been removed from the leading-edge regions of the wing and empennage in about 15 min. This operation is usually accomplished in less time than that required for the warming-up of the engines.

The removal of ice from the wings, after accretions have been allowed to form, sometimes is accomplished satisfactorily, other times with some refreezing on the rearward and unheated portions of the wing.

The installation of the thermal system will result in a loss of climb and speed performance at all times when air is passed through a ram-actuated system. The internal and external losses will have almost a negligible effect on the performance of the airplane if care is used in providing the utmost in aerodynamic cleanliness. A poorly designed installation, on the other hand, can cause a loss of as much as 6 mph in speed at 55 per cent power cruise. The use of alcohol blade shoes on propellers has not resulted in a measurable loss in performance, although it is reasonable to believe that a slight loss in propulsive efficiency has been experienced when the design blade section ordinates are changed to the extent necessary in the heater installation. The blade shoes could be expected to have a greater effect on new and well-designed propellers.

The passage of heated air through a propeller and the discharge of air at the propeller tip cause a slight loss in propulsive efficiency. These losses will depend upon the shape, size, and location of the tip outlet, and the nature of the air passage.

Service experience with the heated wing indicates that the construction involved complicates the problems of repair of the leading-edge region. When damaged by hail, rough ground handling, or bird strikes, the replacement of the double-skin regions is particularly difficult. Normal means of corrosion prevention, i.e., alclad and dichromate primers, have retarded corrosion on three experimental airplanes after two years of operation. Metallurgical inspection of structural parts has not revealed any deterioration in the allowable strength, yield strength, elongation, or cyrstalline structure.

Discussion and Specifications

The results of all tests and experience in this country and abroad indicate that the thermal system can be applied to most commercial and military airplanes in a manner which will retain normal operational efficiency and dependability during conditions of icing.

In order for the thermal system to make a contribution in improved dependability, the airplane must be able to operate in icing clouds or freezing rain at any of the various operating conditions. It is not sufficient that the efficiency of ice prevention in the cruising altitude, for instance, be better than present equipment. An improvement in the protection during cruising would improve the safety, but unless the conditions of take-off, taxi, and landing are equally provided for, the operator will not be able to improve greatly his flight regularity.

The engineer therefore must give care in making the thermal ice-prevention installation in order to assure that protection has been provided for all normal altitudes and conditions of flight. A thorough knowledge of applied operations is a necessity in meeting this requirement successfully.

The evolution in design will alter the application of the thermal system, but it will not change the natural truth of ice being melted by heat. The fundamental seems to have been established.

[3] With a twin-engine airplane.

Preliminary to the statement of detail specifications, an expression (or at least understanding) of the general objectives should be formulated. The general specification should define the degree of perfection, and certain specializations which result from the use to which the airplane is to be put, the climate and region in which it will operate, the class of service, and the civil or military codes, compliance to which is mandatory. These general qualifications frequently are stated in part through other sections of the specification for an airplane but not in sufficiently complete detail to define the general requirements of the ice-prevention equipment. A specific statement on perfection is desirable because the results of tests and experience thus far observed show that the costs of perfect protection for an unlimited flight duration in the most severe conditions, and under conditions of a dual emergency (such as engine failure in addition to icing conditions), may penalize the usefulness of the aircraft to an impractical degree. Economically there is a limit to the perfection of ice protection in somewhat the same manner that there is a limit to the load factor or power loading which can be provided in an economically employed vehicle.

In addition to a statement on the degree of protection desired, the following general specifications are recommended:

0:1 The formation of ice on the airplane in any manner or location which shall reduce the operational efficiency, interfere with regularity of service, or reduce the safety of flight shall be prevented.

0:2 The installation of the equipment shall result in the minimum increase in weight and maintenance, and minimum decrease in speed and climb performance.

0:3 The safety, structural capacity, hazards from fire or gaseous poisoning of personnel, and versatility of the airplane shall not be adversely altered in any degree by the installation of the thermal system.

Aerodynamic Lifting Surfaces. Complete protection for the wings, empennage, and control surfaces will preserve the lift, drag, and pressure distribution of the basic airfoil, protect the operation of mechanisms, maintain flow through leading-edge duct inlets, protect the illuminating qualities of lighting equipment mounted thereon, and prevent damage to or interference with other parts of the airplane due to ice on the wing or to ice which has become dislodged from the wing and flies rearward.

The complete prevention of ice requires that the leading edge be maintained at a temperature above 32 F over all regions on which liquid water may reside. An ideal solution in the evaluation of the heat required might consist of determining how much water will strike the leading edge and over what area of an airfoil at the various water contents and droplet sizes given in Table 2. By assuming all or a specified portion of the water evaporated, the remainder to be abraded away by the airstream; by assuming a specified transition from laminar to turbulent flow as affected by the presence of water on the wing; by assuming the surface to be hydrophobic or hydrophilic, or to what degree of each; and by making other simplifying assumptions of aerodynamic nature, the required external heat-transfer coefficient at various chord points may be approximated. These calculations should be done at several air temperatures and therefore at several water-content conditions as given in Table 2 in order to establish the condition of maximum heat requirement and the optimum distribution for all conditions. In order for this method to be completely rigorous, the calculations should also be repeated for several combinations of wing and power loadings. This process does not seem practical because the data of Table 2 are not and have not been purported to be authoritative, nor have other weather data more authoritative been established. The process is of dubious accuracy because nothing is known about the relation of mass

transfer to abrasion losses or the distribution of this relation along the chord of the wing.

A rigorous solution to the external heating requirements on an airfoil will not be possible in the design of the thermal ice-prevention equipment until the weather conditions, i.e., water-content and droplet size variations with air temperature, have been established and recognized by regulating agencies and until the physical and thermal processes on the wing leading-edge exterior are better understood.

The degree of protection given a wing will depend upon the intensity of heating, the extent, and distribution of the heat, the pressure distribution of the airfoil, surface smoothness and wetability, and other factors. The specification should allow freedom in design which will permit the engineer to take advantage of all artifices and fortuitous circumstances. For example, in the propeller-wake region, it may be permissible and desirable to discharge the heated air from the leading-edge system into the boundary layer at about the 15 per cent chord point and thus greatly improve the thermal effectiveness of the system.

The experience gained thus far with the thermal system has shown that airplanes equipped with exhaust-heat exchangers will have been provided with protection for the lifting surfaces if sufficient heat is delivered to the 10 per cent chord leading-edge area to produce 100 deg F skin temperature rise at 18,000 ft altitude, 0 F ambient air, long-range cruise power, and in clean air. In the airplanes with which this experience was gained the heated air was passed through the after region of the wing after it had served its purpose in the leading-edge system. The effect of passing the air through the after section may not be large. It is obvious that some benefit will accrue, however, just as it is obvious that a greater heated chord coverage than 10 per cent will give a more efficient use of the heated air.

Practical limitations of wing leading-edge construction require an internal exchange system similar to the Junker's leading-edge intercooler design and therefore predicate within certain limits the type of distribution of heat which can be achieved with air or gas as the heating medium. While the distribution of heat may not be optimum as transmitted to the outer skin by the Junker's intercooler design, neither is the distribution as obtained particularly wasteful of heat. By tapering the passage of the air gap, a nearly uniform outer-skin temperature can be obtained. The conductivity of the skin will even out peaks or valleys which result from large or small transfers on the inner or outer surface at particular chord points.

A specification for the aerodynamic lifting surfaces such as the following is recommended:

1:1 A thermal system of ice protection shall be provided which shall preserve all of the aerodynamic, mechanical, and control characteristics of the wings, horizontal stabilizer, fin, and all control surfaces.

1:2 The degree of protection shall be equal to or better than that afforded by that quantity of heat which will raise the leading-edge 10 per cent heated region average temperature 100 deg F above static ambient air temperature for the condition of 60 per cent engine rated power at 18,000 ft pressure altitude and maximum load, less fuel required to climb to 18,000 ft pressure altitude.

1:3 All air-duct inlets, outlets, breathers, exposed mechanical devices, and illuminating fixtures on or in the surface shall be provided protection equivalent to that afforded the leading-edge areas as specified in 1:2.

1:4 The intermittent operation of the thermal system as presently designed for the aerodynamic lifting surfaces shall not be allowed except during emergency let-down and landing operations.

Windshield. The practical application of the heated windshield has been extensive and therefore the preparation of specifications for this part of the ice prevention does not involve as many questionable issues as other parts with which service experience is limited. The double-glazed windshield, which is heated by the passage of heated air between the panels, has provided protection but is subject to many faults. Freedom in design is desirable therefore in order that new and better solutions to the problem may be developed in service. The wording of the windshield specification should allow this freedom. Since the air-heated system is the principal method now available, the specification should also seek to stimulate the improvement of this method by manufacturers who desire to continue its use.

The external air film, infrared electric heating, electric conducting transparent film, and embedded resistance-wire electric heating all show promise and may replace the double-glazed arrangements.

Specifications for windshield ice prevention are recommended as follows:

2:1 Means shall be provided through the use of heat whereby the vision of the pilots through the cabin transparencies will not be reduced by the formation of ice, frost, or fog on inside or outside, in any maneuver in flight or on the ground.

2:11 The provision of adequate vision at all times must be achieved without the use of knock-out panels or the opening of windows.

2:2 The heating of the pilot's windshields shall not impair the comfort in the cabin of the airplane or cause irritation to the eyes, nose, or throats of personnel in the pilot's cabin.

2:3 The prevention of ice on the windshield should be accomplished without the resort to water repellents on the outer surface of the glass.

2:4 The operation of the thermal ice-prevention equipment shall not reduce the protection which is afforded by the windshield to the cabin occupants against bird impacts and similar hazards.

2:5 The construction of the heated windshield shall not seriously impede the cleaning of the windshield glass.

2:6 The heating of the windshield shall not cause an optical distortion of the pilot's view.

2:7 The heating of the windshield shall not cause an accelerated deterioration of the plastic binders of safety glass or of elastic or plastic frame seals of the panel in the airplane.

2:8 The protection against ice on the windshield should be equal to or better than that which is afforded when 1000 Btu of heat per sq ft per hr is passed through the outer surface of the transparency at an indicated airspeed of 150 mph.

Propeller Blades. Although the quantity of heat required for the protection of the propeller blades has not been evaluated by analysis, experimental data have been collected whereby adequate specifications can be prepared. As in the case of other equipment previously noted, freedom of design should be permitted because there are several ways in which the thermal system can be employed with apparently equal results. Ice on the blades of a constant-speed propeller reduces the efficiency of the propeller at all blade angles and also reduces the blade angle in accordance with the increase in drag of the blade section. Protection of propellers therefore should be as nearly perfect as possible.

The Army Air Forces Specification No. 29245, November 15, 1945, may well serve as a guide in the detail specifications of the blade-heating equipment. The specifications as follows are also recommended:

3:1 Means shall be provided whereby the propeller blades shall be heated in a manner and to a degree which shall prevent

the loss of propulsive efficiency or excessive propeller unbalance by ice formations or damaging shedding of ice fragments at all operating conditions in the air or on the ground.

3:11 The prevention of ice on a propeller which is feathered shall not be required.

3:2 The protection on the propeller blade should be equal to or better than that which is afforded by the continuous dissipation of 3.2 w per sq in. average over the leading-edge 20 per cent chord region and 75 per cent of the span measured from the hub face, or by the intermittent dissipation of 3.5 w per sq in. over the same area.

3:3 The construction of the blade-heating system shall provide for a heating intensity on the leading-edge one-third of the heated area which is double that on the rear two-thirds.

3:4 The propeller-blade heating installation or its operation shall not cause a reduction of the normal propeller efficiency.

3:5 The construction of electrically heated blade shoes shall allow for trimming of the tip end when this region has become abraded by wear.

3:6 The passage of heated air through a propeller blade shall not cause an apparent increase in the propeller noise level.

3:7 The operation of the propeller ice-prevention system during reverse pitch braking is not required.

Miscellaneous Parts. Specifications for the provision of protection on regions and parts, the formation of ice on which does not create at once a direct hazard, are recommended as follows:

4:1 The formation of ice on the front of the fuselage, engine nacelles, propellers, spinners, or hubs shall be prevented if ice formations on these parts, individually or collectively, cause a significant reduction in the performance of the airplane, or if the formation causes danger to, or malfunctioning of, the affected part or any other part of the airplane.

4:2 The formation of ice shall be prevented by thermal means on the fuselage, and other places not otherwise specified, from which dislodged ice formations may cause damage to other parts of the airplane.

4:3 Radio antennas and masts should be located so as to minimize the formation of ice thereon, and the strength of these parts should provide for carrying maximum ice formations without structural failure.

4:4 Provision shall be made for the intermittent removal of ice from all protuberances, antenna wires, masts, and extending mechanisms when such formations reduce the specified performance of the airplane or adversely alter the operational usefulness of the airplane.

Specifications for the protection of minor functional parts are recommended as follows:

4:5 Provision shall be made for the prevention of ice formations by thermal means on air speed total- and stati-pressure orifices, on the mast supporting such instruments, and on the surface of the airplane where flush-type static orifices are employed.

4:6 Wherever possible, air-intake scoops should be designed so as to eliminate the vulnerability of the scoop to ice formations, otherwise provision shall be made for the prevention of ice by thermal means from air-inlet scoop and guide vanes within air scoops.

4:7 Provision shall be made for shielding all exposed mechanisms not otherwise protected from the formation of ice, the formation on which would cause damage or malfunctioning to the mechanism.

Engine Air-Induction System. The protection against ice in the engine air-induction system is considered to be of first importance by pilots and operators. No other phase of the icing problem can affect the performance and safety as suddenly and dangerously as does ice in the carburetor and other induction parts. The provision of satisfactory protection has been handicapped because of the circuitous channels of procurement and divided or questioned responsibility. Protection for the induction system involves considerations of engine, carburetor, airplane design, and airplane operations. In the past, the engine and carburetor have frequently been designed without consideration of the ice problem. In other instances, false claims have been made which have misled the pilots until authentic operating data were available.

The only satisfactory solution to the induction icing problem is one in which no ice is allowed to form during all operating condition. The operation of the system should not adversely alter the performance of the airplane and should not limit the operation of the engine when ice is being prevented. Whereas these requirements are important in consideration of reciprocating engines, they are even more important when turbine type engines are employed.

Recommended specifications for the protection of the engine air-induction system are as follows:

5:1 Provision shall be made for preventing the accumulation of ice in the engine air-induction system through the use of thermal means.

5:11 The thermal system of ice prevention shall provide for the heating of the walls, exposed parts, and protuberances in the induction system,to, or above, the freezing temperature of water; or

5:12 The thermal system of ice prevention shall provide for the heating of the engine air to a temperature above the freezing point of water at all points along the path of air flow.

5:2 The use of the thermal system shall not limit the power rating or manifold pressure at which the engine may be operated when the system is in use.

5:3 The use of the thermal system shall not reduce the power of the eingine (because of a reduced ram pressure in the engine manifold) to an extent which will reduce the operational efficiency of the airplane.

5:4 The operation of the thermal system shall not require adjustment by the pilot of the airplane nor shall any attention from the crew be required by the equipment while it is in use.

5:41 Required thermal modulation, where not inherent in the system, shall be provided by automatic devices.

Miscellaneous Mechanical Equipment. Good mechanical design of aircraft is a production of good engineering administration, a willingness on the part of the manufacturers to allow adequate time for design and tests of new developments, and an accurate statement by the operator who buys the airplane of the anticipated requirements. Some detail mechanical specifications are desirable, however, several items of which follow:

6:1 A source of heat or power for each component of the thermal system shall be provided which will have adequate capacity for all normal and emergency operating conditions and for all meteorological conditions to be encountered.

6:11 Operating conditions in which the thermal system shall be required to function are engine warm-up, taxiing, take-off, climb, climb with one engine inoperative, cruise at all loading and power conditions, cruise with one engine inoperative, 400 fpm let-down with 45 per cent or more engine power, 400 fpm let-down with one engine inoperative, and landing.

6:2 Provision shall be made to protect the airplane structure and equipment, which will be in contact with the circulated heating medium, against corrosion from active ingredients contained therein.

6:3 In so far as the output of the heating source is not inherently modulating, provision shall be made to limit the maximum temperature of the circulating medium to 350 F.

6:4 Provision shall be made, in systems employing exhaust gas-air heat exchanger or exhaust gas-air mixing equipment, to close the hot-air duct if a fire occurs in the engine nacelle.

6:41 In event of fire in the engine nacelle, the hot-air duct shall be closed with a stainless-steel valve by automatic means.

6:5 Provision shall be made for easy access to the equipment of the thermal system, for easy inspection, and for the repair of the wing and empennage leading edges, ducting, and valves by normal aircraft sheet-metal shop practices and without excessive cost.

6:6 An indication of good duct design shall be when the pressure losses in the duct do not exceed those occuring in the heat exchanger, combustion heater, or wing leading-edge internal heat-transfer system.

6:7 Provision shall be made to prevent the absorption of liquids such as hydraulic fluid or oil into the thermal insulation of hot-air ducts.

6:8 Only such insulating materials may be employed on the ducts which are fireproof, contain no volatile oils, and which do not deteriorate when subject to aircraft vibration.

6:9 Flexible fabric connectors may not be used in the air duct system.

Acceptance Tests. The approval and acceptance tests of the equipment should be given careful consideration in the specifications. Although the only permanent proof of acceptability will be satisfactory protection in ice over a long period of service, preliminary tests on one airplane can serve to show approximately the thermal qualities and therefore the ice protection to be afforded. It should be noted, however, that the only practical time to change the thermal ice-prevention system is when it is still on the drawing board.

Recommended specifications for the acceptance tests and instrumentation of the thermal system are as follows:

7:1 The capacity of the thermal system to produce and distribute the required quantities of heat to the protected components shall be demonstrated prior to flight tests and preferably prior to the assembly and fabrication of the components into the airplane.

7:11 The capacity of the thermal system shall be determined from airflow rates and air-temperature measurements.

7:12 The flow rate to each component of the thermal system shall be within 5 per cent of the designed flow rate when the rate through the air inlet is in accordance with the design value.

7:13 The quantity of heat delivered to each component of the system shall be within 10 per cent of the design value.

7:2 The capacity of the thermal system to modulate the air temperature within specified limits shall be demonstrated in accordance with the performance demonstration as specified in 7:1.

7:3 The measurement of temperatures may be by thermocouples and manual or automatic recording potentiometers.

7:4 Installations employing exhaust-gas exchangers or gas-air mixing devices shall demonstrate that the back pressure on the engine is within allowable limits, that specified temperature modulation is achieved, and that the capacity of the heat source is adequate for all conditions as specified in 6:11.

7:50 A demonstration of the control system shall be made prior to flight wherein all normal and emergency contingencies which may be encountered will be simulated.

7:51 The control system shall cope with all operational contingencies with the safety of the airplane and personnel maintained.

7:60 The performance of the thermal system shall be demonstrated in flight in dry air and in stratus-type clouds.

7:61 Flight-performance tests shall demonstrate the normal and emergency operation of all controls, burners, heaters, valves, safety devices, and equipment of the thermal system.

7:62 Flight-performance tests shall demonstrate that the heat is properly distributed to the various components of the heated system.

7:621 The demonstration of heat distribution shall be made in dry air, and stratus clouds at kinetic temperature above 32 F, and in cloud conditions as obtainable at kinetic temperatures between 0 and 32 F.

7:70 Provision shall be made and procedures outlined in printed form whereby all components of the thermal ice-prevention system may be observed in operation and inspected when the airplane is at rest on the ground.

7:80 The thermal system should be equipped with a means of indicating in flight that heat is or is not being supplied to the wings, empennage, and propellers. The indicator shall be within the full view of the pilot's, copilot's, or flight engineer's station.

Conclusion

The use of the thermal ice-prevention system involves many aspects of heat transfer. The progress which has been made in establishing a solution to the problem has, in large part, been due to the interest which has been given to the application of the thermal system by engineers who have given special study to this branch of engineering.

The use of the thermal system, however, has not been different from most other engineering applications of heat in that the problem involves many considerations which require a knowledge of other branches of engineering. In our present case, the aerodynamics of the wings, the propulsion of the propeller, the metallurgy of the structure materials, the economics of operational aeronautics, and many other branches of knowledge, which are important fields of specialization, must be considered.

The specifications and comments enumerated above cannot be expected to be complete in all detail. They do call attention, however, to many features of the thermal system that might otherwise not have been considered by engineers who have not had the opportunity to follow closely the research and development work on this problem. Giving to the design engineer in the factory and the operations engineer in the air line the most complete statement of the experiences of the research work should enable us to obtain the best equipment, at the least cost, and in the shortest time.

Acknowledgment

In the use of all information in this paper, acknowledgment is given to the N.A.C.A., by which the data were established, to the Army Air Forces and the Bureau of Aeronautics which sponsored many of the projects, and to the air lines and manufacturers who have faithfully encouraged and supported the work on the ice problem.

The Escher Wyss-AK Closed-Cycle Turbine, Its Actual Development and Future Prospects

By CURT KELLER,[1] ZURICH, SWITZERLAND

This paper is the first comprehensive presentation in this country of details of the gas-turbine process employing a closed cycle. In spite of grave handicaps entailed by the war, the development of this turbine proceeded from the first experimental installation in 1939, to the advanced designs which are now available for industrial application.

Introduction

UNLIKE combustion turbines little has so far been reported in the United States about the gas-turbine process employing a closed cycle. The first plant of this kind was completed in Switzerland during the summer of 1939, just before the outbreak of war, namely, an experimental installation of 2000-kw useful output, Fig. 1. The enforced seclusion of Switzerland during the last 6 years, and more especially the interruption of communications with America made it impossible to discuss this new AK-plant, developed by the Escher Wyss Engineering Works in Zurich according to proposals made by Ackeret[2] and Keller.

However, in spite of the many difficulties arising from the war, it nevertheless proved possible to try out the experimental plant until normal industrial operation was reached and to investigate fully all its components.

About a year ago Prof. H. Quiby (the successor of Professor Stodola at the Swiss Federal Institute of Technology in Zurich) carried out exhaustive official performance trials on the new plant. A report (8)[3] on these trials was published in June, 1945. These official trials represent the termination of the first phase of internal scientific development, and the results obtained have justified in every respect both the theoretical and practical expectations. Projects embodying such a closed-circuit plant for power generation or ship propulsion can now be realized, on the basis of the preliminary studies extending over a number of years, without unwarrantable technical risks being involved. The questions that arise in this connection and the constructional solutions which we consider suitable from the technical point of view will now be mainly dealt with.

Since 1939 a number of original publications have been made regarding the theoretical and physical basis of the AK-process, which are now also accessible to American engineers (several of these articles have already been printed in English). The Bibliography of the chief papers regarding this field, together with the short index at the end of this paper, are quite comprehensive.

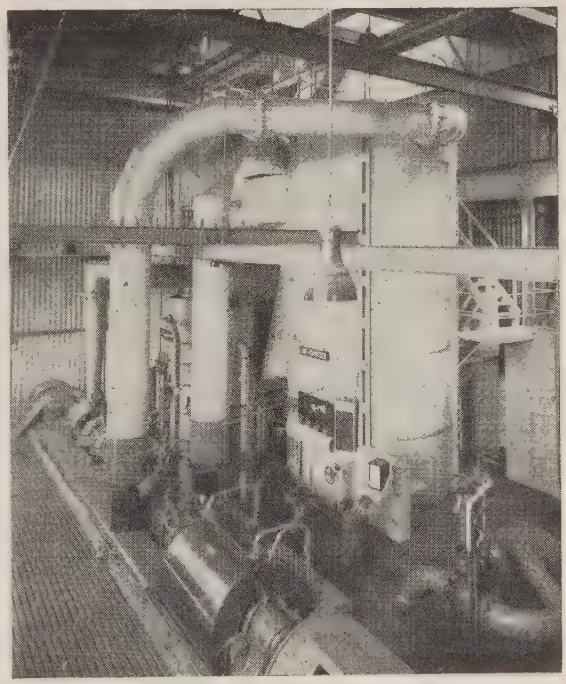

Fig. 1 General View of the First 2000-Kw Experimental Plant at Escher Wyss Works in Zurich, Switzerland

It will suffice therefore to give a brief summary of the chief characteristics of the new process as an introduction. Some information, but not all the data, was provided in a preliminary report which was read by R. T. Sawyer and discussed by S. A. Tucker during the June, 1945, meeting of the Society.

In recent months we have been favored by a number of visits from American engineers who came to the Escher Wyss Works, where information concerning the development work in connection with these AK-plants was given, and the trial installation itself was explained. As a consequence, our work in this field has become known among a wider circle of specialists.

The publications hitherto made with regard to the basis and development of the AK-process will be supplemented for the first time in the present paper by referring in greater detail to studies and designs, so far not published, for closed-circuit units which from the technical point of view are now practicable, and by remarks concerning the later uses and further possibilities of development. Since the research work and the whole field for such installations are very extensive, it is possible within the framework of the present paper to discuss only the principal ideas on the basis of examples.

Contributed by the Oil and Gas Power Division and presented at the Annual Meeting, New York, N. Y., November 26–29, 1945, of The American Society of Mechanical Engineers.

Summary of Theoretical and Physical Bases of Closed Circuit and Its Particular Features

As in the case of all other gas-turbine processes, it is our endeavor to approach as closely as possible the thermal efficiency of the ideal process for thermal prime movers, namely, the Carnot process, and furthermore with means which are simple in practice and at the same time economical. The closed gas cycle offers favorable possibilities for realizing this aim.

In the case of air or other technical gases the Carnot process proper, Fig. 2, is accompanied by numerous practical drawbacks, because for attaining the high initial temperatures T_1, which modern steels are capable of withstanding, very high pressure ratios P_1/P_2 from 200 to 300 have to be dealt with, especially during the adiabatic compression, which is difficult to realize in turbomachines.

The AK-process endeavors to bring about a cycle, the so-called double-isotherm cycle, which is thermodynamically equivalent to the Carnot cycle for gases. Fig. 3 illustrates this cycle in comparison with the Carnot cycle proper. The AK-process employs only small pressure ratios between A and B for isothermal compression of the air. Further adiabatic compression between B and C, according to Carnot, is intentionally dispensed with and replaced by an internal exchange of heat at constant final pressure of the preceding isothermal compression. The supply of heat from an external source by the combustion of fuel shall, as in the Carnot process, take place exclusively along the isotherm C-D. After this expansion with simultaneous development of power, the heat is reimparted to the gas along B-C by internal heat exchange in the circuit itself, whereby the pressure remains constant. This double-isotherm circuit has exactly the same theoretical efficiency as the Carnot cycle and is, consequently, dependent only upon the temperatures

$$\eta = \frac{T_1 - T_2}{T_1} \text{ (absolute temperatures)}$$

But the high pressure ratio, which is such a drawback, is entirely avoided; it can be reduced to a small fraction of the foregoing value, and one is not bound to a given relationship $P_{\max} : P_{\min}$ for attaining the maximum temperature T_1.

The hatched surfaces $ABCD$ in the entropy diagrams, Figs. 2 and 3, illustrate the work obtained for each unit weight of gas (air) for the Carnot circuit and for the double-isotherm circuit. This work is the difference between the turbine output $D'C'CD$ (= heat supplied from external source Q_{in}) and the compression work $A'B'BA$ (= heat carried away in cooling water Q_{out}). The relatively large proportion of compression work in the case of gas processes is clearly shown by the entropy diagram.

Complete isothermal compression and expansion can, of course, be only approximately realized in the machines that are available in practice. However, compression and expansion by stages, with intermediate cooling or heating (indicated by dotted lines on the AK-diagram) permit of this aim being put into practice to a considerable degree with only a few stages. The average temperatures T_1' for the supply and extraction of heat T_2' do not then deviate very considerably from the highest and lowest temperature of the ideal circuit. At the same time, the chief requirement of the thermal law is still largely fulfilled, namely, that the whole heat shall be imparted to the working medium at high temperature, and the remaining heat, after the development of power, be extracted at as low a temperature as possible.

An important new feature of the AK-process lies in the fact that the working medium is not taken from the atmosphere and afterward returned to the ambient air, as occurs in the case of all old reciprocating machines employing hot air, as well as in open-circuit gas turbines. Furthermore, since the AK-circuit is closed, it works with higher pressure of which the lowest pressure at the compressor inlet already lies considerably above atmospheric pressure. The chief characteristics, namely, a double-isotherm circuit with high-speed turbomachines and heat exchange, heat supply from an external source and raising of the

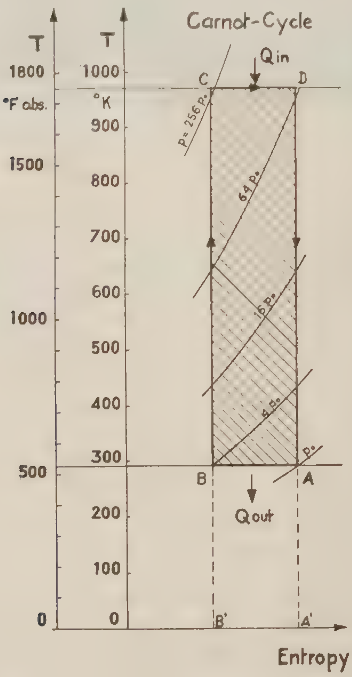

Fig. 2 Entropy Diagram of Carnot Process for Gases

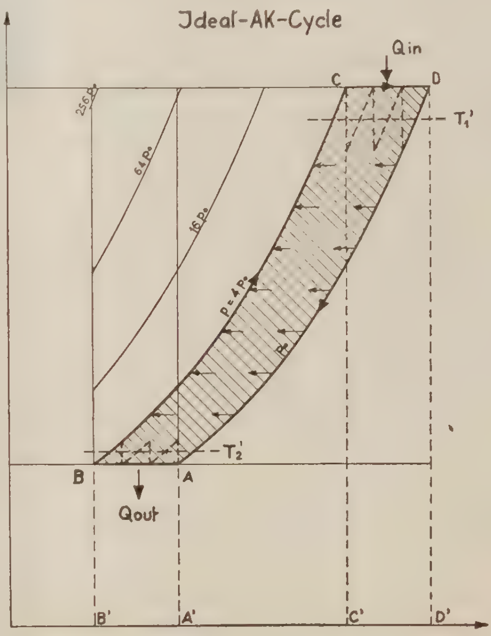

Fig. 3 Entropy Diagram of AK-Process With Complete Regeneration, Which Is Equivalent to Fig. 2

pressure level, have decisive consequences for the realization in practice, to which reference will now be made.

To illustrate the fundamental difference between the method of operation of the ordinary combustion turbine and the closed circuit of the AK-plant, simplified layouts for these different installations are compared with one another in Figs. 4 and 5. In

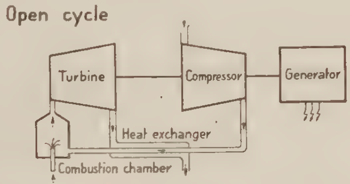

Fig. 4 Schematic Diagram of Open Circuit of Combustion Turbine With Heat Exchanger

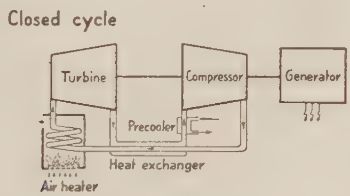

Fig. 5 Schematic Diagram of Closed Circuit of AK-Plant

place of the combustion chamber, the closed-circuit system has an air heater which is heated from an external source, corresponding to the boiler of a steam-turbine plant. In comparison with the open-combustion turbine which discharges its waste air to the open, the only additional component of the AK-plant is a precooler which cools the working medium after it has passed through the turbine and heat exchanger, to as low a temperature as possible before being reinhaled by the compressor. The principal features of our process and the characteristics resulting therefrom may be summarized as follows:

The Closed Pressure Circuit. Soiling of runner or impeller blading as well as of heat-exchanger surfaces by combustion residue or other foreign matter is completely eliminated, which provides a guarantee that the efficiency of the machines and the heat-transmission coefficients will remain unchanged. The working medium, which is always clean, permits the adoption of small cross sections for the elements of the heat exchangers.

The system is so supercharged that the pressure at the suction branch of the compressor already lies considerably above atmospheric pressure. As a consequence of this supercharging the dimensions of all parts of the plant, both machines and heat exchangers, are considerably reduced, on the one hand owing to the smaller specific volume of the working medium, and on the other hand because of the considerably increased heat-transmission coefficients at a higher pressure. Such supercharged operation permits of the unit outputs being increased almost without limit.

External Heating. By separating the circuit of the working medium from that of the combustion air it becomes possible to employ any kind of solid, liquid, or gaseous fuel, such as bituminous coal, lignite, oil, or gas.

Output Regulation. The output of the plant can be varied by changing the pressure level without altering thet emperatures and while maintaining the efficiency practically unaltered at all loads. By raising or lowering the pressure level (brought about by temporarily supplying or extracting working medium to or from the circuit), the plant can be suited to any desired part load, simply by changing the density of its working medium. In doing this the flow conditions in the machines, the pressure ratios, the velocities, and the angles of attack to the blades remain practically unchanged, the same being true of the internal efficiency. Hence the machines always operate at exactly the same point of their pressure-volume characteristic. Consequently, the efficiency of the plant is almost equally high at part loads as at full load, only the constant losses arising from bearing friction and heat radiation being proportionately more pronounced at part loads.

The fact that the temperatures remain unchanged at all loads is a particular advantage for the practical operation of such plant at high temperatures. No regulating valves, etc., are provided in the circuit proper, i.e., either on the machines or auxiliaries. The means for controlling the supply and withdrawal of air, which is stored in cold compressed-air accumulators, are united in a regulating set outside the circuit of the working medium and are traversed only by cold air.

The Use of Other Gases. Other working media than air can be adopted only in the case of a closed circuit with an external supply of heat. The employment of suitable light gases, such as helium, for example, opens up the possibility of increasing the output of the plant for the same dimensions, or of further raising its efficiency, as a consequence of the particular physical characteristics of such gases for special purposes (drive of transport means or aircraft).

Operating Cycles of the AK-Process

The simplest air turbines operate with direct expansion in the turbine itself and with two intermediate coolers in the compressor, as may be seen in Fig. 6. The most favorable pressure ratio

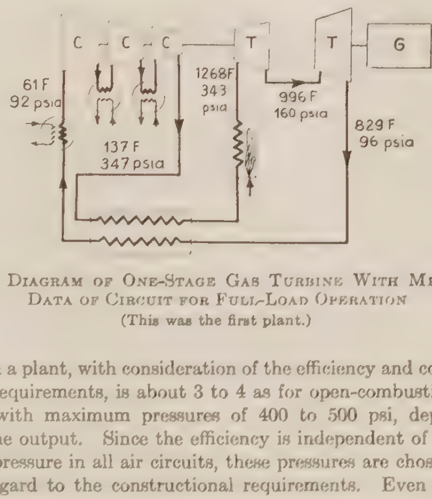

Fig. 6 Diagram of One-Stage Gas Turbine With Measured Data of Circuit for Full-Load Operation
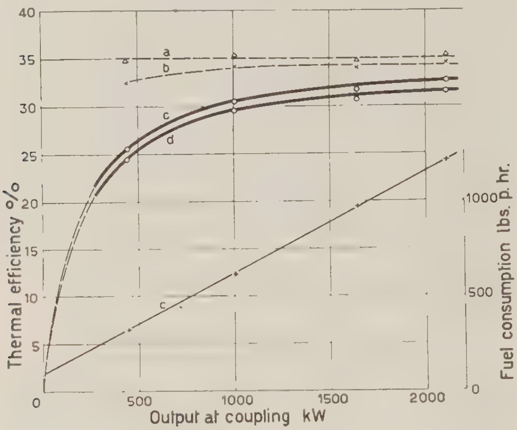
(This was the first plant.)

for such a plant, with consideration of the efficiency and constructional requirements, is about 3 to 4 as for open-combustion turbines, with maximum pressures of 400 to 500 psi, depending upon the output. Since the efficiency is independent of the absolute pressure in all air circuits, these pressures are chosen only with regard to the constructional requirements. Even for the largest outputs no very high pressures are necessary, i.e., such as are encountered in steam turbines. For initial temperatures from 1200 to 1400 F, the discharge temperatures from the turbine are not higher than 750 to 950 F, so that no special alloyed steels are necessary for the heat exchangers. The example provided by the experimental plant proves that noteworthy thermal efficiencies can even now be attained with single-stage designs.

Fig. 7 shows the thermal efficiency which was measured during the official performance trials on the first experimental plant. In this connection it should be borne in mind that when this experimental plant was projected the chief intention was to try out the principle itself and test the co-ordination between the various components of the circuit. As a consequence of the in-

tended experimental work, the plant was laid out to insure easy accessibility to all parts thereof, so that measurements could be carried out without difficulty. Consequently, neither the arrangement nor the space requirements of the experimental plant may be taken as a criterion for later industrial installations which can be made much more compact.

The Sankey diagram, Fig. 8, shows the course of the heat quantities flowing through the various parts of the plant. Such a diagram applies in a similar manner to all single-stage installations. For each 1000 kw the AK-plant requires about 20 lb per sec working air in the circuit. In installations of larger output or to meet demands for higher efficiencies, we employ two-



a) Efficiency without insulating and bearing losses
b) Efficiency without bearing losses
c) Efficiency without auxiliaries
d) Net efficiency all losses included
e) Fuel consumption

(Curves indicate effect of relatively large bearing and insulation losses as well as power needed for auxiliaries)

stage expansion with intermediate heating which can be easily put into effect, as the following examples demonstrate:

This two-stage expansion represents a further and sufficient approach to the double-isotherm process which it has been endeavored to realize from the beginning with the AK-process (see Fig. 3). Intermediate heating, or double heating, as we refer to it in the case of the AK-plant, brings about a saving in fuel of 10 to 15 per cent. Considerations of a theoretical and practical nature lead, in the case of double heating, to the increased pressure ratio of about 10.

As a result of the greater pressure ratio and consequently the larger heat drop in the case of double heating, with due consideration of the losses in the circuit, not only a considerable increase in the thermal efficiency is realized, but at the same time a further reduction is accomplished in the dimensions of the machines and auxiliaries. This applies, in particular, to the heat exchanger because the weight of the circulating working air per unit of output is considerably smaller (approximately 12 lb per sec per 1000 kw), and because the greater pressure ratio allows of larger pressure losses without reducing the efficiency.

Fig. 10 shows the conditions in the case of direct expansion (A) and double heating (B), with due consideration of the losses. The circuit with double heating (B), can be thought of as realized in practice by placing two single circuits (A) next to one another. If in both instances one takes the same values for the limit temperatures T_1, T_2, with the same machine efficiencies η_T, η_K but with twice the pressure losses $\epsilon_B = 2\ \epsilon_A$ and temperature differences $\Delta\ t_B = 2\ \Delta\ t_A$ in the recuperator for the case (B), then the course of the efficiencies applies for (A) and (B) equally, if only the pressure ratio is taken as abscissa for (A) and for (B) the square of this ratio. The definition of ϵ is $\epsilon = \dfrac{\Delta p}{p_1}$, $\epsilon_2 = \dfrac{\Delta p}{p_2}$

Δp = pressure drop on high-pressure side with pressure p_1, or low-pressure side, p_2.

With reference to Fig. 9, curves 2 and 3 have been plotted for two different pairs of values Δt, ϵ. Assuming the same difference in temperature, for example Δt = 36 deg F, and the same pressure losses ϵ = 10 per cent with direct expansion and double heating, the difference between curves 2 and 3 indicates the improvement by double heating. In the technically useful field of suitable pressure ratios, it amounts to 4 per cent absolute.

As already pointed out, the quantity of air in circulation becomes smaller owing to the greater pressure drop for double heating, so that the heat-exchanging surfaces are likewise reduced. If in the case of (*B*) one intentionally renounces to a certain extent an improvement in efficiency by allowing greater temperature and pressure losses as a consequence of increased velocities, the conditions will be those of the field between 2 and 3. However, in this way the surfaces of the heat exchangers as well as the other dimensions can be reduced considerably.

Installations with double heating operate according to the schematic diagram, Fig. 10. The corresponding Sankey diagram, Fig. 11, shows the reduced quantities of heat which are conveyed in comparison to Fig. 8. In actual installations, maximum pressures of 400 to 600 psia with back pressures of 40 to 60 psia will be adopted for small outputs, whereas for larger outputs above 10,000 kw, the pressure is raised to a maximum of 850 psia with about 85 psia back pressure. In this case also, the heat drops are so distributed that the heat exchanger can be built without requiring the use of special alloyed steels. The power stations and marine plants subsequently referred to operate according to this circuit.

Examples of Typical Components of Closed-Circuit Plants

Although the duty of the various machines and apparatus remains fundamentally the same in all installations, various designs nevertheless result which are dependent upon the different outputs required, the uses to which the installations will be put, the efficiencies and the available fuels. The closed cycle, operating at a pressure above atmospheric, leads to conditions of construction which deviate considerably from other kinds of gas and steam turbines. The consistent application of knowledge gathered from the laws of flow, from up-to-date aerodynamics, and also concerning the improved properties of metals subjected to high temperatures, coupled with proper harmonizing of the various components, has in recent years led to ever-increasing simplicity for our designs. They deviate in many respects from the layouts usually encountered for turbomachines. An AK-plant is not simply an assembly of known components; the arrangement of the various parts in relation to one another and the course of the working medium through the whole installation are the subject of careful study, whereby due attention has been paid to heat expansion. Only in this way can the pressure losses in the pipings and the other secondary losses be reduced to an admissible measure.

In this connection it has proved advantageous that all parts of an AK-plant such as the turbines and compressors, as well as the heat exchangers and air heaters, form part of the actual manufacturing program of Escher Wyss, which specializes in the construction of turbomachines of all kinds. Thus all the components have been developed and built in the company's own works, the experience gathered in various fields being duly coordinated and proper use made of the latest research results obtained in the company's own hydraulic and caloric laboratories.

It should also be borne in mind that AK-installations are quite suitable for standardization. Thus for example, the whole range of stationary installations from 3000 to 50,000 kw can be dealt with by a few types of machines and auxiliaries. The component parts of the heat exchangers themselves as well as the regulating means can, for installations of these various sizes, be put together in suitable combinations. This standardization which has been attempted but never realized in the case of steam turbines will have a favorable influence on the price calculations.

(The effective output of this turbine is 34,000 kw.)

duced owing to the raised working pressure of the closed circuit, the machines are astonishingly small when compared to open-circuit combustion turbines. In addition, the heat drop that has to be dealt with is much less than in the case of steam-turbine plants, so that the closed-circuit turbine has not many stages.

For informatory purposes the main dimensions of the rotors for standard AK-plants of various outputs have been indicated in Table 1. These dimensions may vary slightly according to the speed and blading (action or reaction) of the turbine, whether an axial or radial compressor and of course also in accordance with the pressure that is employed. For the greater part, however, the sizes of the machines will not prove very different from the figures indicated in Table 1. The fact that no regulating valves or stop valves are fitted to the machines leads to favorable conditions for the construction of such hot-air turbines.

This permits the adoption of constructional forms for the turbines which differ considerably from those usually employed for

steam turbines, Figs. 12 and 13. Special attention has to be paid to the inlet and outlet losses which, as a result of the small pressure and temperature drops that are utilized, play a relatively important part. The absence of regulating devices permits of the turbine being situated, literally speaking, immediately in the piping which conducts the working medium, an arrangement with which one is familiar in the construction of hydraulic machines.

It is possible, for example, to pass the working medium through an inlet branch supply pipe to the first runner wheel without employing annular channels. The outlet can be made symmetrical and a considerable part of the kinetic energy can be recovered, for instance in spiral outlet casings as in hydraulic turbines or pumps. Such forms are also used for the axial-flow compressors. The small turbines also permit the adoption of double casings which are designed according to the same principle as the hot-air piping previously referred to. Between the thin internal shell and the external casing there is a layer of insulating material; the internal casing serves only for conducting the hot current, while the cold external casing takes up the pressure. The whole guide apparatus is fixed to the casing at a point where temperatures are low. In this manner the external casing is, even for high inlet temperatures, subject at the most only to the discharge temperature of the last stage (approximately 925 F). Thus although the turbine-inlet temperature is much higher, heat-resisting steel need not be adopted for the casing but only for the small internal parts.

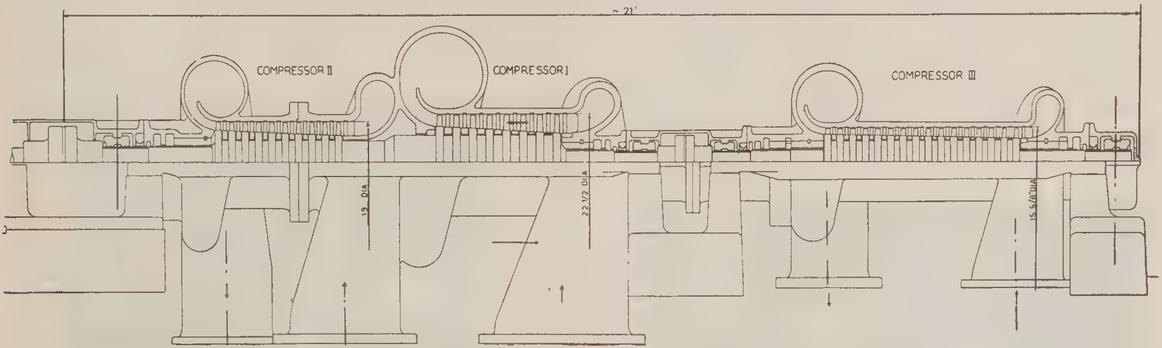

Fig. 14 Cross Section Through Axial-Flow Compressor for 25,000-Kw Set
(n = 6000 rpm.)

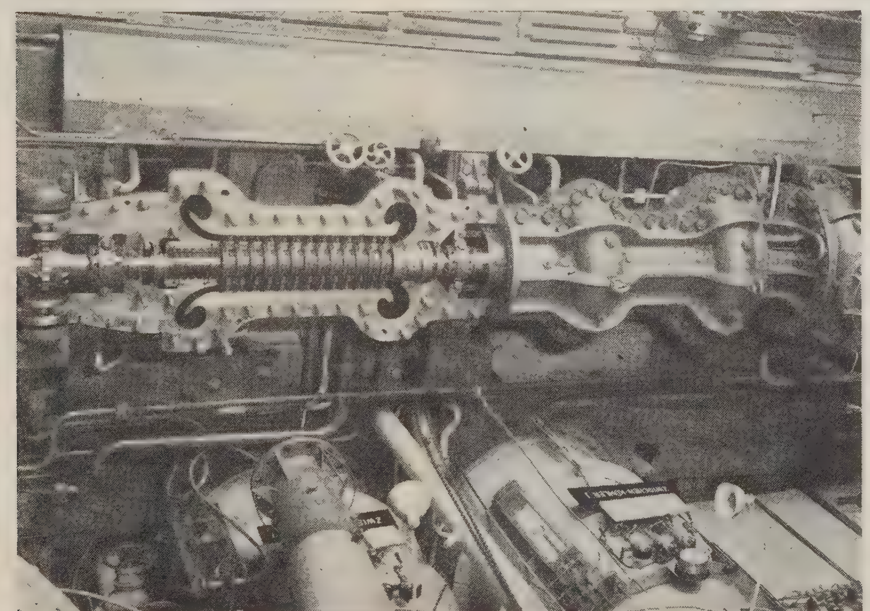

Fig. 15 View of Axial-Flow Compressor With Streamlined Inlet and Outlet Casing
(AK-Test Plant.)

Similar constructional principles, dictated by the latest knowledge in the field of flow techniques, apply also for the compressor and for the intermediate coolers forming part of the latter, Fig. 14.

Since relatively large quantities of air but small increases in pressure have to be dealt with, up-to-date axial-flow turbocompressors of the multistage type are particularly suitable for such duty. The high speeds needed for this type of compressor lie within limits which offer good constructional conditions also for the driving turbine. As a result of these high speeds the compressor set is of small dimensions even when dealing with the largest volumes. It has been possible to raise the efficiency of the bladings above the values attainable with radial compressors. This is again the outcome of systematic research in this particular field, Fig. 15.

As turbine and compressor always and at all loads work at the same operating point, high-quality blading need only be developed for this one point without compromises. For these conditions the course of the pressure-volume characteristic for part loads need not be considered. For the same reasons, for instance, in the case of small outputs of other gases, radial compressors can also be adopted thus leading to fewer stages.

Figs. 16 and 17 illustrate typical blading for AK-turbines and AK-compressors having stage efficiencies of more than 90 per cent. As a consequence of the raised pressure the Reynolds numbers of the machine bladings are of a considerably higher order, so that the percentage of friction losses becomes smaller. This holds good only for smooth and clean surfaces. Tests in our laboratories on a full-sized axial compressor inhaling ambient air, containing only usual workshop impurities, have proved that the blade efficiency dropped from 86 to 83 per cent during 12 hours continuous operation.

The rotating shafts of the machines are sealed from the ambient air by means of labyrinth glands or a combined system of labyrinth glands with liquid sealing, depending upon the size of the plant and the kind of gas employed. Good sealing is necessary in consideration of the losses, especially at smaller outputs or when employing special gases.

The glands illustrated in Fig. 18 have proved their merits in the case of the experimental plant. Sealing air extracted from the circuit is passed through a pipe to the labyrinth chambers. The pressure of this sealing air is at all loads always somewhat higher than the pressure inside the glands, corresponding to the point where it is bled from the circuit. In this way it becomes impossible for hot air to escape. From the point where sealing air is introduced another part branches off toward the exterior of the gland and flows into a collecting space which is connected to a point in the circuit where a somewhat lower pressure pre-

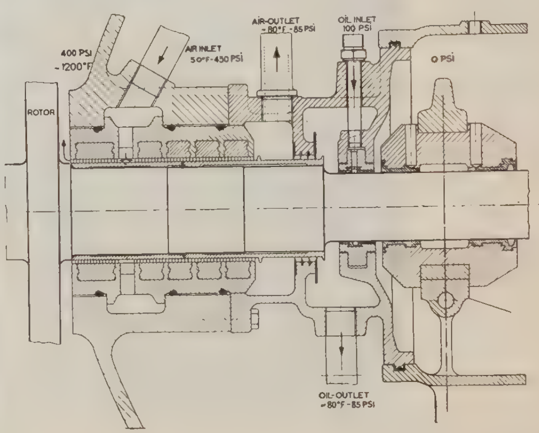

Fig. 18 Combined Labyrinth-Liquid Sealing for High-Temperature Turbines

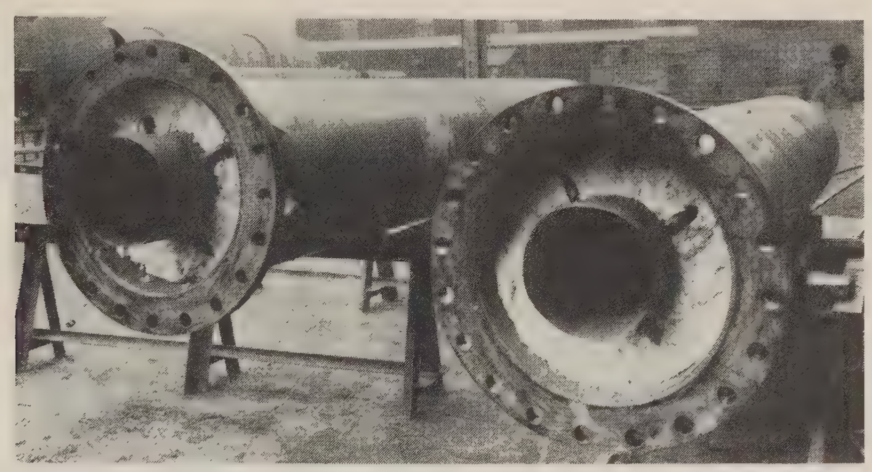

Fig. 19 Double-Shell Piping for High-Pressure Hot Air

vails. Outside these air-sealed labyrinth glands there is a ring through which oil under pressure is supplied to the shaft. This pressure oil prevents the escape of any air from the circuit. On either side of the pressure oil ring means are provided for leading the oil to a reservoir, which is under a suitable pressure above atmospheric, since it is connected to the interior of the circuit. The oil-sealing ring can also be combined with the bearing itself. By suitable connections of the sealing air pipes to the circuit it is possible to insure that at all loads, i.e., at all pressure levels, the sealing pressures will likewise rise and fall automatically, and that the direction of the current will remain the same; this without regulating valves of any kind having to be interconnected.

In practice the foregoing is very important for insuring the safety of the plant. The measures described have proved fully satisfactory in trial operation under the most exacting conditions. The sealing air, introduced to the end sections of the hot turbine shafts, is simultaneously utilized in an advantageous manner for cooling these parts, so that the bearing sections remain quite cold.

Hot-Air Piping. In order to reduce in so far as possible the quantity of metal capable of withstanding high temperatures, the hot-air piping has been made with double walls according to the same principle as for the turbines, Fig. 19. The design comprises a thin-walled internal tube of a heat-resisting material serving only for conducting the stream of gas. By means of openings this tube is relieved from the pressure in the heat-insulating space which surrounds it. The heat-insulating space in its turn is enclosed by a thicker-walled pipe of standard material which can easily take up the pressure of the working medium, since it is protected by the insulating material and therefore it is not under high temperature. The necessary measures are, of course, taken to prevent insulating material from gaining access to the tube. With this design much high-quality and expensive steel can be saved.

Air Heater. In the aerodynamic circuit the air heater plays a similar part to that of the steam boiler in a steam-turbine plant. The heat of the fuel is imparted indirectly to the working medium by heat-transmission surfaces, the combustion gases being kept away entirely from the machines.

Since no feedwater is employed, the air heater can, in principle and in contradistinction to a steam boiler, be installed in the open air without any building, all danger of freezing being nonexistent.

The design of the air heater is dependent upon the fuel that has to be dealt with. Coal-fired air heaters resemble in their design up-to-date steam boilers, as may be seen from the examples, Fig. 20 and Fig. 21. According to the present stage of development, the space requirements of coal-fired air heaters are not greater than those of up-to-date high-pressure boilers.

Fig. 20 shows a section through a coal-fired air heater with granulating chamber. This project for a 12,000-kw plant is conservative as regards the combustion chamber, as well as the stresses and temperatures for the tube walls, since care in this connection appears necessary for the first installation. It may, however, be definitely expected that subsequent developments will lead to the heating surfaces and the dimensions being considerably reduced. The inlet temperature of the tube nest in the convection section amounts to only about 1850 F. By returning the flue gases in the combustion chamber, its temperature is regulated and reduced. The tubes have diameters of approximately $1^1/_2$ to $^3/_4$ in. and have wall thicknesses of 0.15 to 0.1 in.

Fig. 21 shows a project for a plant of the same output with liquid-ash extraction and increased temperature in the combustion chamber for utilizing the radiation. The walls of the combustion chamber are lined with short tubes of small diameter. The air passes through them at high velocities so that the wall temperatures nevertheless remain sufficiently low, to permit of their being subjected to the radiation without further protection. In view of the fact that the waste gases from the air heater have relatively high temperatures as a result of the highly preheated circuit air, their waste heat is employed for preheating the combustion air. The use of preheated combustion air leads to an increase in the furnace temperature, particularly in cases where pulverized coal is used. For example, in plants burning pulverized coal such preheating of the secondary air is desirable since it permits a reduction in the size of the combustion chamber.

It is not purposed to deal further herein with the details of coal-fired air heaters, since our studies and investigations in this connection have not been completed in all respects. Experimental equipment for air heaters with pulverized-coal firing is being subjected to experimental work in Zurich. The behavior of ash and slag on hot tubes is being particularly studied. The results so far obtained justify the opinion that pulverized-coal firing will not present any fundamental difficulties for the AK-air heater.

Oil- or gas-fired heaters can be made more compact. In the case of the latter the possibility exists, especially where space is restricted as in marine installations, of supercharging the com-

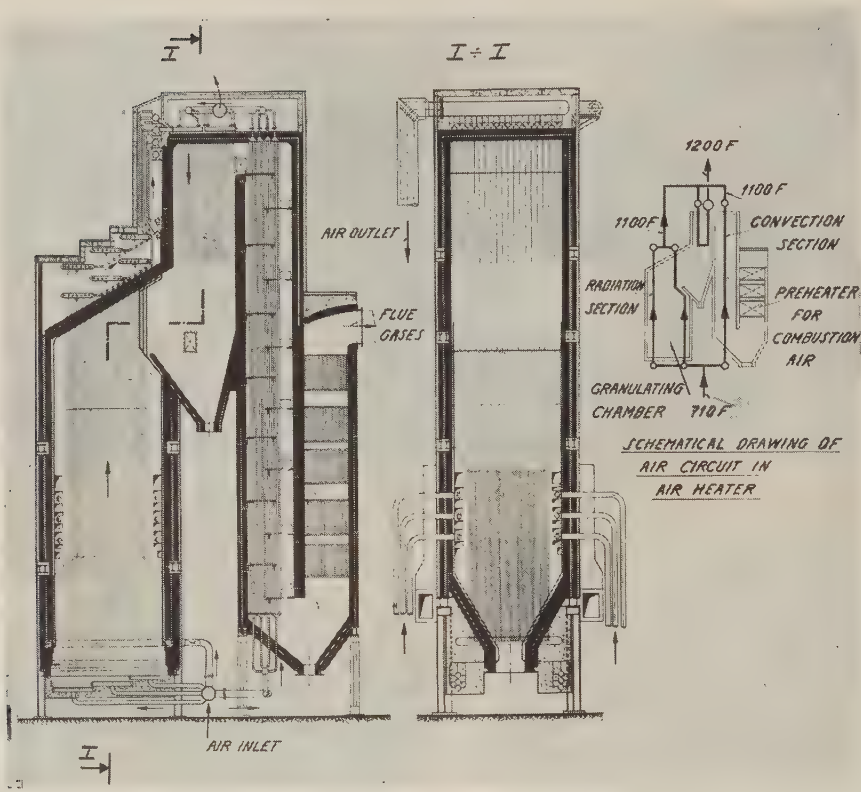

Fig. 20 Air-Heater for Coal-Firing With Granulating Chamber

bustion chamber by which means the dimensions and weights can again be considerably reduced (down to one half the surface) compared to ordinary firing.

Fig. 22 shows an example of an oil-fired air heater for a 6000-kw plant with 600 psia and double heating. The tubes are arranged around a supercharged combustion chamber. The tube walls for heating the air in the first stage and in the second stage, 600 psia and 200 psia, respectively, are united in a common heater. In the case of this project the combustion chamber is lined with refractory material, and the heat is given up to the tubes mainly by convection. By raising the pressure of the combustion gas to about 45 to 70 psia, and with velocities of combustion gases from 100 to 160 fps, and air velocities inside the tubes from 65 to 130 fps, the heating surface can be kept small. For such projects it amounts to only 0.5 sq ft per kw net output of the plant.

The total weight of iron in such an air heater is less than 9 lb per kw. Of this figure the proportion of alloy steel is about 50 per cent. The tubes, which may expand in operation by about $2^1/_2$ in., can move freely in the upward direction. In order to keep the hot-air piping as short as possible the heated air for the high-pressure turbine and low-pressure turbine is discharged below. The shell of the heater is of ordinary steel and made airtight. It can be dismantled in a number of sections so that the tubes are easily accessible from the side and can be removed without difficulty. The shell serves at the same time as a support for the tubes.

Since the waste gases are still of high temperature (approximately 1000 F), they are expanded in an exhaust turbine and simultaneously cooled. The exhaust turbine drives the compressor for the combustion air. In this way a preheater for the combustion air can be entirely eliminated. The supercharging set need not be particularly efficient because most of the losses are recovered in the firing. As there is no regenerator there is little danger of detrimental soiling. The design of an air heater employing blast-furnace gas or natural gas is, for the greater part, the same as for oil-firing. The heating surfaces are likewise quite similar.

The design of the air heater according to Fig. 22 corresponds in principle to the one which has proved its merits in the experimental plant from the beginning, only with the difference that in the latter case firing under pressure was not adopted, for the sake of simplicity.

The working medium which has passed through the heat exchanger is supplied to the air heater always in a highly preheated state (600 to 750 F). However, the supply of heat does not bring about any change in condition (evaporation) as is the case in the steam boiler. Evaporating elements, large collectors, and the drums of steam boilers can therefore be dispensed with. Since the air is under pressure, the employment of tubes as heating elements is found to be the most satisfactory means. According to the fuel adopted and the temperature in the furnace, the heating surface is subdivided into a radiation section and a convection section.

In view of the fact that a gaseous medium has to be heated by means of combustion gas, higher tube-wall temperatures have at first to be considered than in the case of steam, where, as a result of the high heat-transmission coefficients on the water and steam side, the tube-wall temperatures are not much higher than the steam temperatures. The working pressures at which the

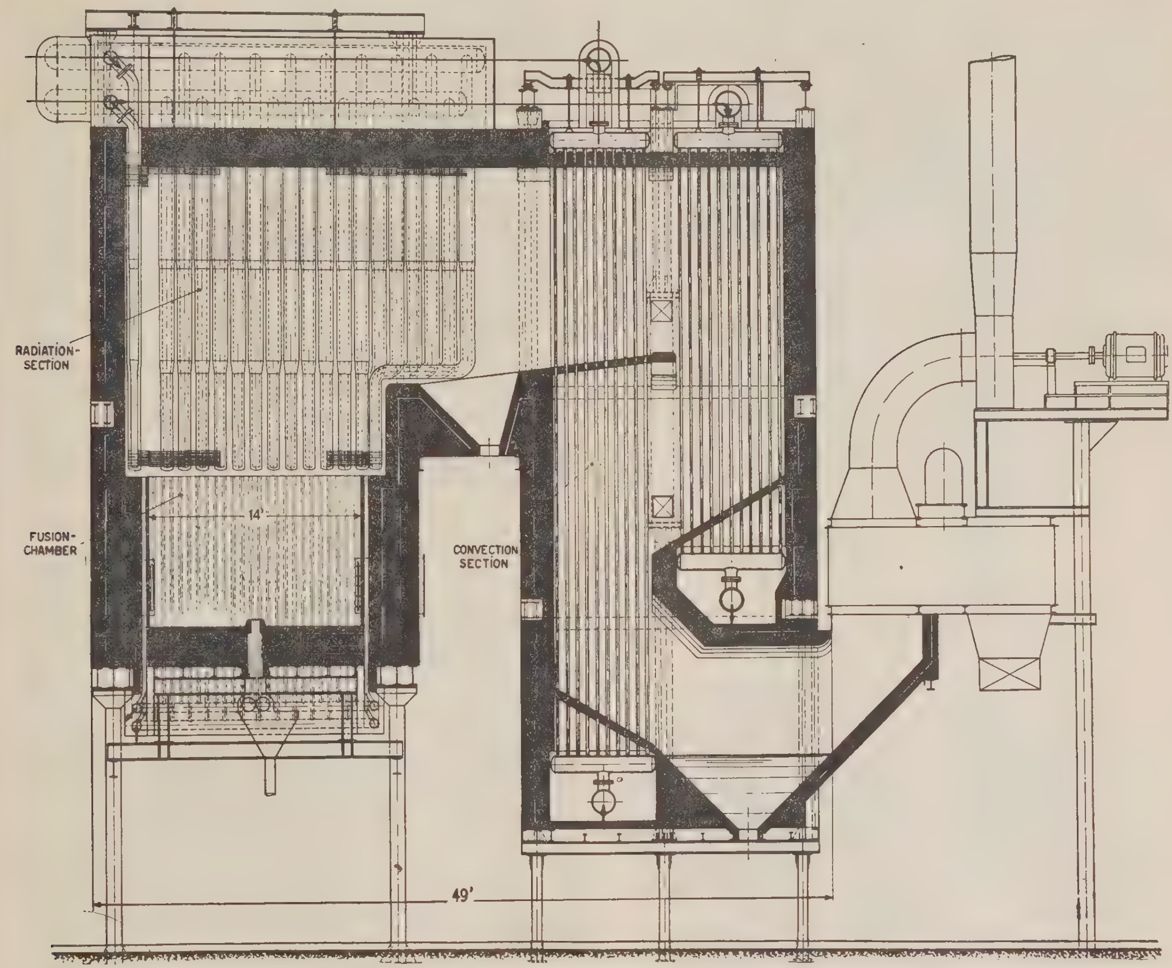

FIG. 21 AIR-HEATER WITH FUSING CHAMBER FOR PULVERIZED COAL

closed cycle operates have the same effect. The heat-transmission coefficient in the interior of the tubes can be so great that the tube-wall temperature is displaced to a considerable extent toward the cold side and comes within ranges to which alloyed steels nowadays obtainable on the market can be subjected without hesitation. The maxi mum temperature of the hottest tube wall can be forced down to 70 to 100 deg F of the final temperature of the air. The heat-transmission coefficient for the interior of the tube is

$$\alpha = c\,(w \cdot p)^{0.75}$$

where

c = constant factor
w = velocity
p = pressure

and accordingly proportional to the product $w \cdot p$.

Thus for the same velocities the heat-transmission coefficient, compared to conditions at atmospheric pressure, increases many times, for example, at 400 psi to 12 times, at 850 psi to 22 times. For practical cases heat-transmission coefficients of 100 to 200 Btu per sq ft per deg F per hr for the interior of the tubes can be reckoned with. Fig. 23 shows, by way of example, how for the same-percentage pressure drop $\epsilon = \Delta\ p/p$ per unit length, the tube-wall temperatures automatically fall as a consequence of increased pressure in the interior without velocity increase, so that the air-heater tubes can be subjected to the duty in the combustion chamber without special cooling measures being necessary.

A simple means for compensating for excessive combustion-chamber temperatures is a return circuit of the flue gases to the combustion chamber, whereby practically any desired temperature can be adhered to. This has been effected also in the oil-fired air heater of the test unit of 2000 kw.

It is often assumed that a very high velocity and a considerable detrimental pressure drop are necessary in the heater tubes for carrying away the quantity of heat. However, as a consequence of the pressure action and with suitable layouts this is by no means the case. For the air heater of a 400-psi plant the pressure drop is only about 10 to 15 psia; at 850 psi for two-stage heaters it totals 20 to 30 psi.

If the flow velocities in the interior of the tubes could be increased at will, any desired reduction of the tube-wall temperature down to the temperature of the air current inside the tubes could theoretically be envisaged. But this can be attained only with a loss of over-all efficiency.

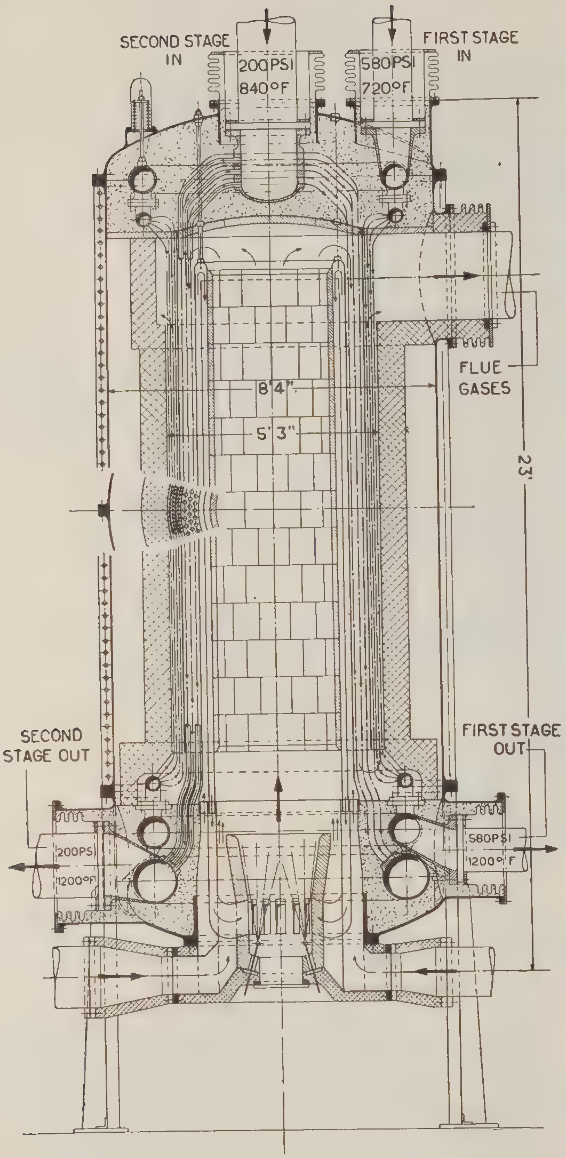

Fig. 22 Oil-Fired Air Heater for 6000-Kw Set Supercharged

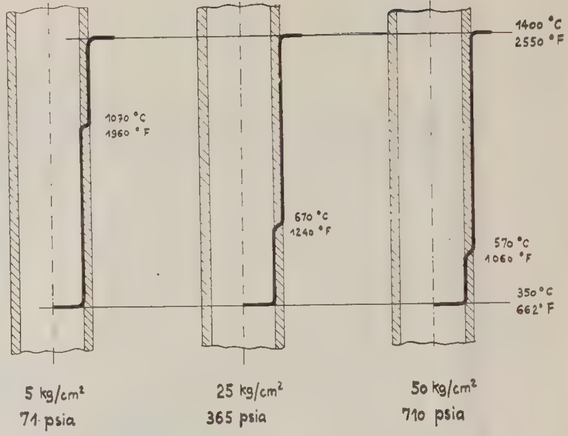

Fig. 23 Influence of Inside Pressure of Air-Heater Tubes on Wall Temperature

An increase in the velocity involves the need for minimum pressure losses. Thus the velocity in the various heater sections will be increased only to such an extent as is necessary for attaining the admissible tube-wall temperature. This knowledge leads to the adoption of tubes having different diameters which are suited to the various ranges of temperature.

Careful calculations of all these problems have led to a series of fundamental circulation layouts for the working medium to be heated and for heating combustion gases. The wall temperature can be further reduced by suitable layouts employing countercurrents, parallel currents and transverse currents in the various heater sections.

Fig. 20 illustrates one of the many solutions that can be adopted in this connection. The countercurrent to be heated is subdivided at the inlet into two parallel currents, one of which, mainly subjected to radiation, flows as a direct current and the other, the temperature of which is raised by contact with heated parts, flows as a countercurrent to the flue gases. This brings about a reduction of temperature in the hottest sections. At the same time the subdivision into two or more parallel currents permits a considerable reduction in the total pressure losses. The two partial currents pass into a common final heater and collector pipe.

If it is desired to avoid excessively high temperatures in the radiation section, the pipes can be arranged in such a manner that final heating takes place in the section heated by contact, where the tubes are protected from the effects of radiation.

Only a part of the air heater must be made of special high-quality materials. In this connection the fact should not be lost sight of that for the working pressures concerned the wall stresses are astonishingly small (2500 to 4000 psi), even with thin tubes. Those figures still lie far below the creep limits of good alloy steels for the corresponding temperature ranges.

Heat Exchanger (*Recuperator*). Unless a heat exchanger is employed it is hardly possible to increase the thermal efficiency of any kind of gas turbine plant above about 20 per cent. The quantity of heat that has to be given up by the current of gas issuing from the turbine to the current of gas after the compressor at full regeneration is of the same magnitude as the quantity of heat which in the air heater is introduced from an external source.

The heat-transmission coefficients on both sides of the heat-exchanger surfaces are raised considerably in the case of the supercharged closed cycle. In combination with the small specific volume this offers possibilities of reducing considerably both dimensions and weights. A further point is that one can in principle adopt very small cross sections for the tubes, or other fine exchanger elements, because any danger of soiling is entirely eliminated.

The conditions for constructing a good heat exchanger of small dimensions are doubtless more favorable for a closed circuit than for gas turbines with which the flue gases pass through the heat exchangers. Apart from the high blading efficiency of the machines, the easy realization of a very high heat exchange is one of the chief reasons for the high over-all efficiency of closed-circuit installations, even when employing moderate temperatures.

In practice heat-transfer coefficients of 30 to 50 Btu per sq ft per deg F per hr, depending on the admissible pressure loss, may be taken as a basis. These figures are multiples of the heat-transfer coefficient characteristic of the heat exchangers for com-

bustion-gas turbines. For economical reasons one is compelled not to go too far with the recuperation in the case of the last-mentioned plants, since space and weight for the construction would become too great. According to available figures, such new two-stage installations require about 3 times or more heating surface. With the closed cycle we find surfaces of 1.5 to 3 sq ft per kw sufficient, depending upon the pressure, and furthermore for an over-all efficiency of the plant exceeding 33 per cent; the degree of recuperation being about 90 per cent. It is possible to bring the weight of the heating surfaces down to even less than 2 lb per kw. The following illustrations likewise indicate clearly that the heat exchangers of closed-circuit installations are relatively small.

In principle, any kind of heat-exchanging surface (flat or tubular), and any means for conducting the current can be adopted. However, since the plant operates under pressure, the use of simple steel tubes which can be manufactured at relatively low cost represents the given means for effecting this transmission.

Fig. 24 illustrates the design of a tubular exchanger operating according to the countercurrent principle and transmitting a maximum amount of heat with a minimum loss of pressure. The high-pressure air flows through the interior of the tubes and the external shell has to withstand only the lower back pressure. The apparatus can be arranged as desired, according to the available space or subdivided into two or more parts. The use of normal tubes of small diameter permits standardization of all heat-exchanger elements for the various outputs and thus to a large degree manufacture in series.

We employ tubes of only 0.15 to 0.25 in. diam. They are separated by special spacers which offer little resistance to the current of air. A large number of these thin tubes is assembled in a tube nest. In their turn the latter are connected by a small number of collector pipes. Separate removal of each tube nest is easily possible. In the case of stationary plants this can be effected, for example, by drawing the various tube sections out of the heat exchanger in an axial direction. For marine installations the shell of the heat exchanger is split and can be easily lifted, thus giving access to the tube nests from above. The tightness of each nest can be checked separately. However, since a perfectly clean medium flows on either side of the tube walls, there is no reason to fear interruptions in the operation.

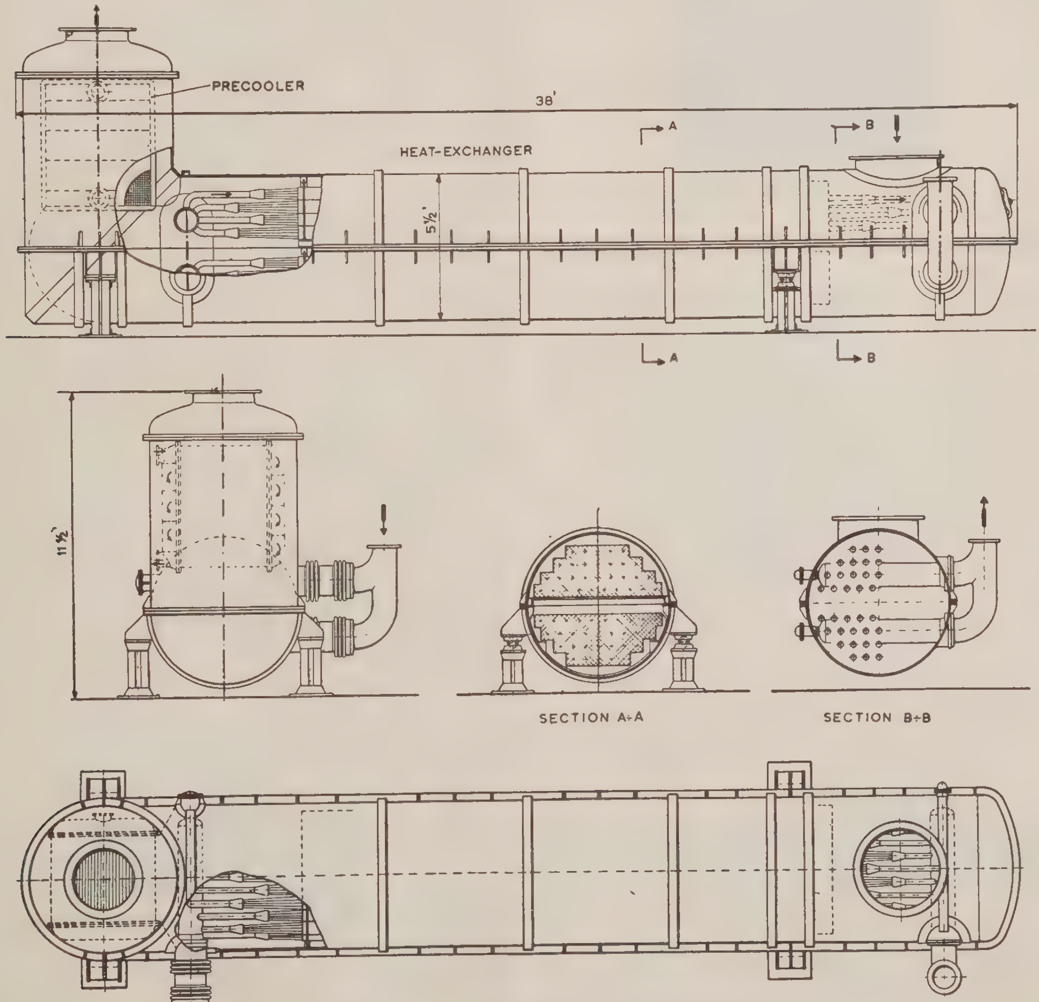

Fig. 24 Heat Exchanger or Recuperator for Closed-Cycle Unit, Built Up of Small-Diameter Tubes

Furthermore, the highest temperature in the heat exchanger amounts only to about 850 F, so that it is unnecessary to employ special-quality metals for the tubes. Fig. 25 shows a view in the part of the apparatus where the spacers are arranged; as may be noted, the external bright part where the low-pressure air flows is hardly obstructed by these distance pieces.

The temperature of the low-pressure air on issuing from the heat exchanger is about 200 to 250 F, after which it passes to a precooler, through which water circulates, for cooling in so far as possible down to the inlet temperature of the compressor, the object being to reduce the compression work. Since, as a result of the raised pressure the heat-transmission coefficients on the air side are also favorable in the precooler and in the intermediate coolers of the compressor, the surfaces and dimensions of these units are not large, in contradistinction to water-cooled air coolers when operating with small working pressures. Incidentally, the precoolers and intermediate coolers are of

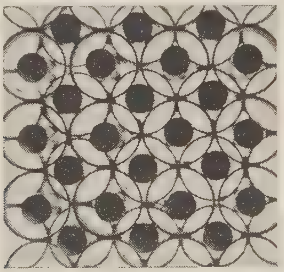

Fig. 25 View of Space Arrangement in Regenerator

standard ribbed-tube design with water circulation through the tubes.

In many cases it is advantageous to combine the low-pressure turbine arranged in the circuit before the heat exchanger in the manner illustrated in Fig. 26. In this way additional pressure losses are avoided and the stream of air passes directly to the tube nests. As may be seen in Fig. 26, the heat exchanger, whether arranged in this or some similar manner, is an exceptionally simple apparatus that operates very reliably.

Governing. For raising the output, air is introduced to the circuit from a high-pressure accumulator of cold air, while for reducing the output, air is withdrawn from the circuit and passed to a low-pressure accumulator. Automatic governing for an installation with rigid couplings between the machines takes place fundamentally as follows: When load is thrown off the consequent rise in speed influences the centrifugal governor (pendulum) which causes the discharge side of the combined inlet-outlet valve to open, Fig. 27, so that air from the high-pressure branch of the circuit issues into the low-pressure accumulator LP. On the other hand, when load is thrown on the plant the resulting drop in speed causes the inlet side of the valve to open, as a consequence of which air from the high-pressure accumulator HP is admitted to the circuit at the same point.

For small reductions in load, and consequently only slight increases in speed, the main valve operates only within a small range without opening either the inlet or outlet. On the other hand, the by-pass valve opens and by-passes air from the high-pressure side of the circuit to the low-pressure side without developing output, so that the useful output of the plant is reduced.

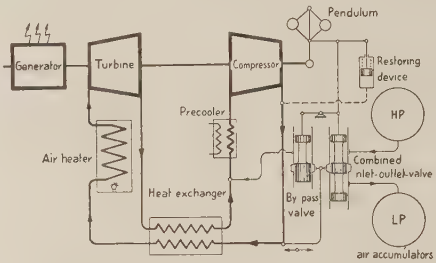

Fig. 27 Scheme of Regulating Device for One-Shaft Machine Set

(Combination of inlet and outlet valve with by-pass valve.)

By regulating small and frequently recurring load fluctuations with the by-pass valve the air consumption from accumulator HP, for purposes of regulation, is reduced and charging work thus saved.

Regulation by supplying or withdrawing working medium to or from the high-pressure side of the circuit has the advantage of immediate efficacy, since the pressure ratio $p_H : p_L$ is immediately raised on air being admitted, thus causing the plant to give up additional output. Inversely, when air is withdrawn from the high-pressure side, the pressure ratio immediately drops, so that for example, when suddenly withdrawing less than 20 per cent of the air content of the circuit, it has dropped to such an extent that the transition from full load to no load has already taken place. On the other hand this "momentary effect" would be unsuitable for the supply or withdrawal of working medium on the low-pressure side.

When admitting or withdrawing air on the high-pressure side of the circuit the consumption of air for such regulating purposes is, in the case of quickly recurring small periodical load fluctuations, no longer proportional to the number of actual load fluctuations and instead increases relatively less, since insufficient time remains between the separate fluctuations for re-establishing the stationary pressure ratio, and the control consequently takes place chiefly under the influence of the "momentary effect," Fig. 28.

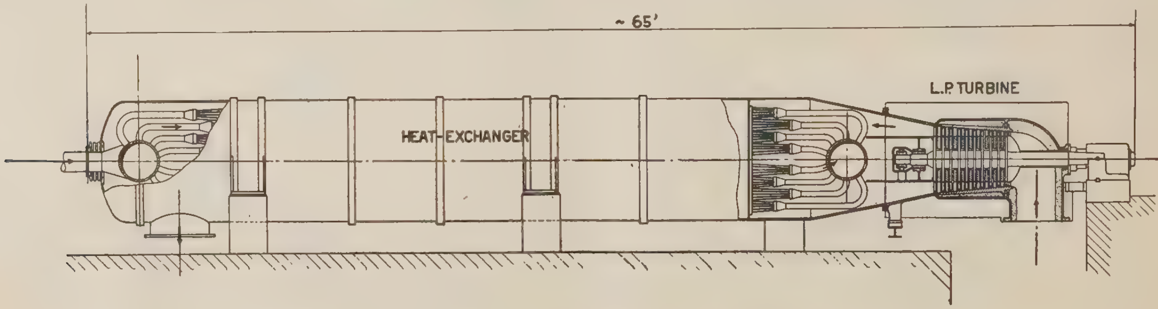

Fig. 26 Combination of Heat Exchanger and Turbine to Conserve Space and Pressure Loss

The influence of the momentary effect on the governing, which for known machine characteristics can also be calculated theoretically, has been checked by experiments. The pressure course, Fig. 29, plotted for a load-reducing action, shows that during the first moment the equilibrium in output is brought about by reducing the pressure ratio $p_H : p_L$; and that the pressure level only gradually drops to the final condition.

The regulation of the furnace, not indicated on the schematic drawing, Fig. 27, need not take place very quickly, thanks to the accumulation of heat in the heaters and apparatus. Changes in the power output of the turbine due to smaller deviations of the final heating temperature of the working air from its stationary value are compensated by automatic and temporary raising or lowering of the pressure level by a small amount.

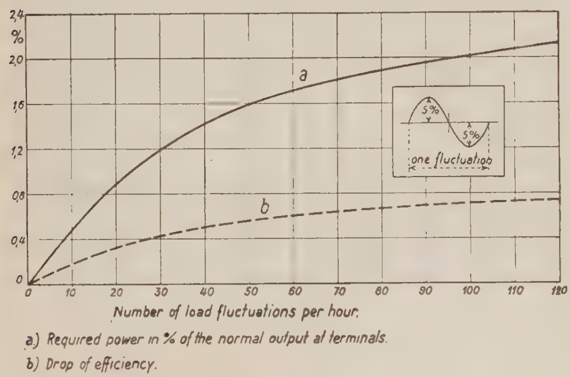

Fig. 28 Power Needed in Per Cent of Net Output for Production of Accumulated Air at Load Fluctuations of ±5 Per Cent

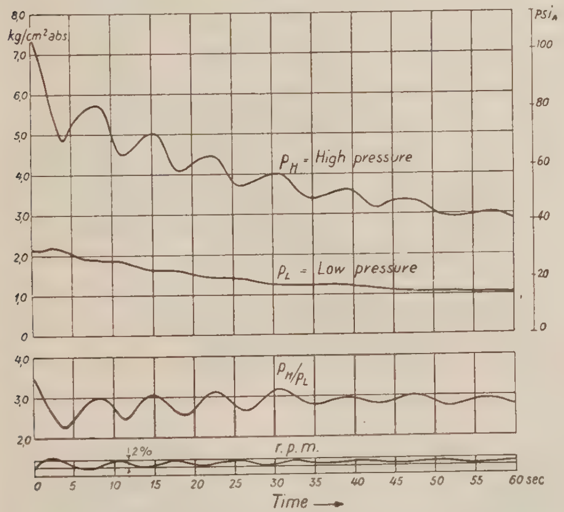

Fig. 29 Pressure Variation at Sudden Load Reductions Reveals "Momentary Effect"

The method of regulation herein described has the advantage that the regulating means can be accommodated in a block outside the circuit proper, Fig. 30, that they are traversed only by cold air, and that under normal working conditions the air of the circuit does not pass through them, so that no additional throttling losses result.

For installations in which the turbine developing useful output is separated mechanically from the compressor set, which is particularly the case where useful output has to be given up at different speeds (for example, compressor drive, ship propulsion), the compressor set operates in the normal operating condition, thus remaining stable and without any special regulation. When the equilibrium is disturbed, i.e., during the supply and withdrawal of working medium for changing the useful output, deviations from a given speed range, either above or below, for the free-running compressor set, are prevented by partly by-passing the turbine developing useful output or the compressor-driving turbine by a special valve actuated from a speed-limiting governor of the compressor set, Fig. 31.

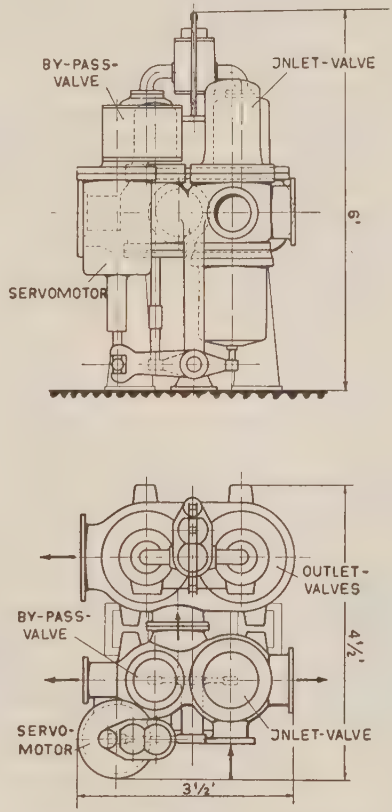

Fig. 30 Regulating Block for 12,000-Kw Set

The test plant has worked for long periods entirely separated from the municipal network and supplying the whole works of Escher Wyss. On these occasions the regulating governing, already in its simplest form, proved to be very satisfactory.

Projects for Power Stations and Marine Plants

The disposition of the various machines and apparatus of an AK-plant within the available space does not involve special requirements. Air is not subject to the force of gravity like steam condensate, so that differences in level, such as are required for insuring passage of the condensate and feedwater, need not be provided for. Thus attention can be paid to a combination of the machines and apparatus in a small closed set with short connecting pipes in order to reduce losses of pressure and temperature to a minimum, of the utmost importance in such plants.

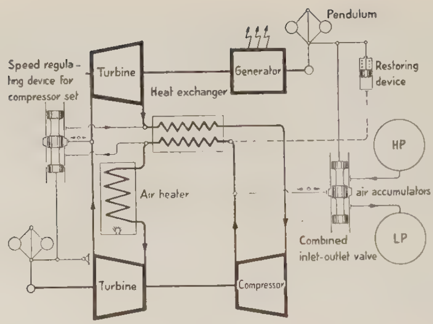

Fig. 31 Schematic Diagram of Regulating Device for Two-Shaft Machine Set
(Marine installations, for example.)

The limited number of auxiliary machines and other accessories greatly simplifies the operation of the plant, whereas in the case of high-pressure steam power stations for high thermal efficiencies, these auxiliaries have become rather cumbersome. The chief factors which bring about a considerable improvement, compared to a steam plant, are the elimination of feedwater, the necessary pumps and apparatus for its preparation, the small cooling-water consumption which amounts to only a fraction ($^1/_5$ to $^1/_{10}$) of that required in steam installations, the elimination of the condensing process with its condensate pumps and air pumps, and the absence of all fittings for very high pressures.

Closed-cycle installations may be operated entirely without water, in that intermediate cooling of the air in the compressor can be effected by employing ambient air as cooling means in place of water. For the large available temperature drops of the intermediate cooling, this arrangement with which cooling water is entirely eliminated, can be realized in an economical manner in contradistinction to steam plants where the condensing process at constant low temperature makes it necessary to endeavor to attain minimum temperature differences when giving up waste heat to the ambient air.

If one takes into account:

1 The relatively small expense involved for special materials capable of withstanding the high temperatures (as a consequence of the small dimensions resulting from supercharged operation);

2 The simple layout of the plant (absence of extensive foundations);

3 The reduced number of accessories;

then it is evident that in spite of the higher thermal efficiency, compared with those of steam plants of the same output, the total costs of the two installations will not greatly differ from one another.

Fig. 31 illustrates, by way of example, a number of AK-installations such as are ready for construction. They are all characterized by high efficiencies, well above 30 per cent. These installations employ pure air as working medium. Fig. 32 illustrates a 12,000-kw plant with pulverized-coal firing for industrial

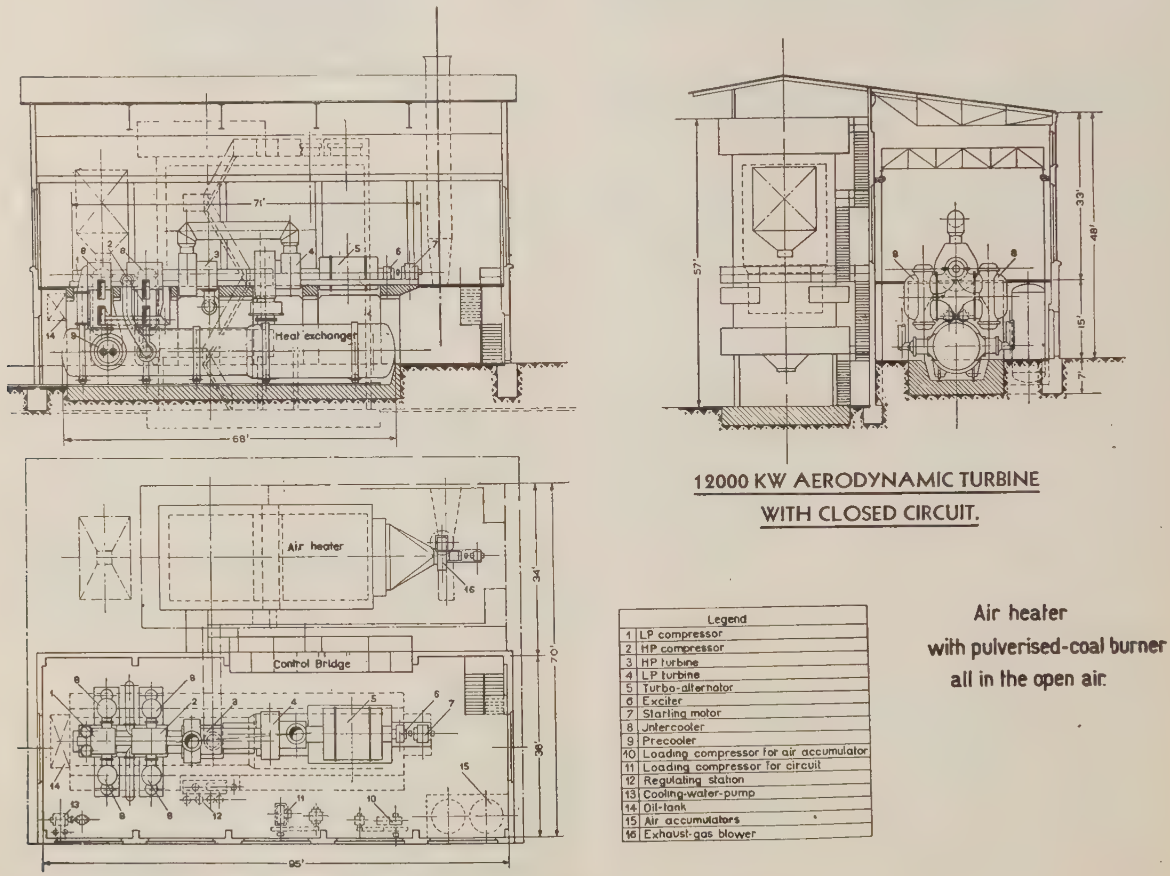

Fig. 32 12,000-Kw AK-Set for Single-Stage Power Plant With Coal-Firing

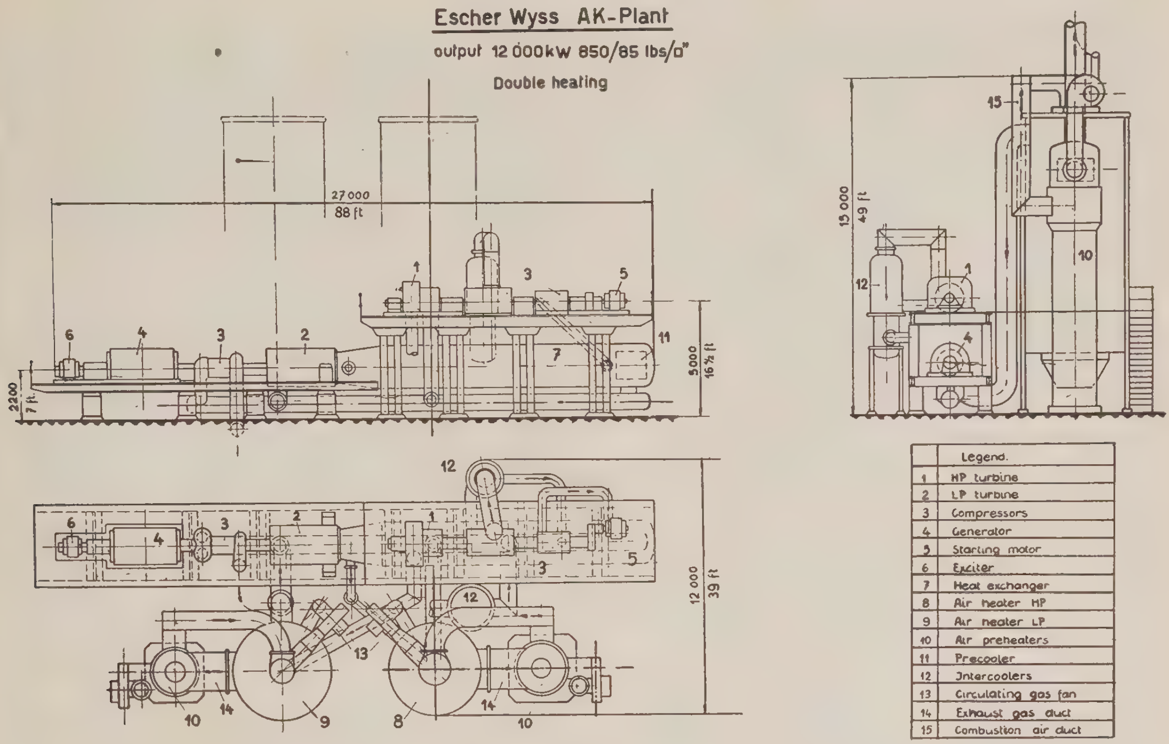

Fig. 33 12,000-Kw AK-Set With Oil- or Gas-Firing, and Intermediate Heating

purposes. The air heater is installed in the open next to the powerhouse, thus considerably reducing the cost of the building. This is a plant with single-stage expansion. The working pressure at full load amounts to 400 F at the turbine inlet, the maximum temperature to 1200 F, and the back pressure to 115 psia. The machines are arranged all in one row. The high-pressure turbine drives the compressor serving the circuit while the low-pressure turbine drives the generator. The heat exchanger is installed underneath the machine set but can of course also be arranged elsewhere, for example, in the open, depending upon the available space. The weight of the circulating air is about 250 lb per sec. All the chief auxiliary drives that are required may be seen in the illustration. Their small number in comparison to the auxiliaries of up-to-date steam power plants is characteristic. The over-all thermal efficiency of such an installation amounts to at least 32 to 33 per cent at full load, still attaining 31 per cent at half load and 28 per cent at quarter load. Naturally these figures vary somewhat according to the quality of the coal.

Fig. 33 illustrates a project for a plant of the same output but arranged for oil- or gas-firing and double heating, the initial pressure being 850 psi and the back pressure 85 psi. The machine plant is subdivided into two independent sets. The high-pressure turbine 1 is fed from the first air heater 8 and drives a part of the compressor rotors. This compressor set is arranged above the heat exchanger 7. The low-pressure turbine 2 drives the generator 4 and the low-pressure part of the compressor 3. The low-pressure turbine and heat exchanger are built together, Fig. 26. The low-pressure turbine receives the reheated air at a pressure of 300 psi from the second air heater 9.

In these stationary installations where the space requirement is not of decisive importance, ordinary furnace-chamber pressures can be adopted for oil- and gas-fired air heaters. This means that the required heating surface becomes larger than for firing under pressure, but on the other hand the charging set is eliminated. In place of the latter an air preheater for the combustion air is adopted. In this case the air preheaters are built as tubular units. The air heaters are arranged immediately next to the machine set proper which leads to favorably short interconnecting pipe work. The fact that no excavation is required for the set and that it rests on a light foundation framework is worthy of note. All parts are easily accessible.

The starting motor 6 has an output of approximately 300 to 400 kw. On the basis of the present state of development, a thermal efficiency, including auxiliaries of 34 to 37 per cent, is attainable at full load and 30 to 33 per cent at one-fifth load. The efficiency is, of course, dependent upon the size of the heat-exchanger and air-heater surfaces as well as upon the cooling-water temperature. For an inlet temperature of 60 F and 160 F exit approximately 40 gal per sec are required. A steam plant of the same output needs about 5 times more. The circulating-air weight is approximately 150 lb per sec.

Fig. 34 illustrates the machine designed for a plant of 25,000 kw output. It remains the same for oil-, gas-, or pulverized-coal firing. Details of the corresponding machines are illustrated in Figs. 12, 13, and 14. The machinery plant can of course be arranged in two sets parallel to one another instead of in a single row, if the available space makes this preferable. When comparing with Fig. 33 it is apparent that the larger output calls for hardly any additional length, since it is primarily the diameter of the machines and auxiliaries which is increased.

An arrangement of the sets in parallel is preferable for marine installations. Fig. 35 shows a marine plant with oil firing for 8000 shp. This plant can be used for turboelectric drive or

for propulsion in conjunction with a variable-pitch propeller. It operates with 600 psi, 1200 F at the turbine inlet, with double heating and supercharged firing of the air heater. The combustion circuit is entirely separate from the working circuit proper, so that they do not influence one another during regulating actions. The reduced strain for the tubes in the case of supercharged firing permits of the wall thicknesses being reduced. The back pressure amounts to 60 psi. The air heater is arranged in front of the machine set. The heat exchanger lies amidships. On the one side is the compressor set for the circuit. It is driven by the high-pressure turbine. On the same side is the charging set for the combustion chamber which receives its drive from an exhaust turbine. The low-pressure turbine is the prime mover proper.

With this arrangement all parts are easily accessible and can be dismantled without difficulty since they all lie in the same plane. When the propeller speed is changed under varying loads, only the speed of the low-pressure turbine is correspondingly altered. The independent regulation of the two machine sets takes place according to the schematic drawing, Fig. 31.

The thermal efficiency of such a marine plant including auxiliaries amounts, at full load and 1200 to 1300 F, to about 32 to 34 per cent, and still attains at one-fifth load an efficiency of 27 to 30 per cent. The weight of the installation in relation to output is approximately 40 lb per shp. The weights, space requirements, and efficiencies are primarily dependent upon the surfaces that have to be adopted for the heat exchangers. The space requirements of a plant, according to Fig. 35, are approximately 2.4 cu ft per hp.

In accordance with present progress in metallurgy it is intended to operate AK-plants at temperatures of 1200 to 1300 F. Every future increase that can be made in the temperatures will, for each 10 deg F, lead to a saving in fuel of 0.75 per cent, i.e., for 40 deg F increase in temperature an improvement in the over-all thermal efficiency of about 1 per cent may be expected.

When making a comparison with open-cycle gas turbines, the pipes passing through the deck which are necessary for supplying the combustion air and for discharging the combustion gases should be borne in mind. Whereas a closed-cycle turbine requires practically the same quantity of fresh air and discharges about the same volumes of waste gas through the funnels as in the case of Diesel engines or steam plants, these volumes are many times greater for an open-cycle combustion-gas turbine because of the large surplus air volume of its working cycle for the purpose of reducing the temperature. Needless to say, the closed-cycle turbine is very suitable for turboelectric drive.

One cannot discuss new gas-turbine developments for marine propulsion without mentioning the future development of the propelling means.

The most suitable solution for reverse operation which, at the same time gives ideal operating conditions for the whole plant, is the adoption of variable-pitch propellers, thus obviating the necessity of installing a separate turbine for propelling the vessel astern. From wide experience in the building of Kaplan-type water turbines, in 1934 we developed such a new marine propeller based upon the same principles. No failures or defects have been reported from the 35 marine propellers already delivered.

Other Fields of Application

Remote Heating. In contrast to the condensing plant of steam turbines, where heating of the cooling water may amount to only a few degrees owing to the necessity of maintaining a good vacuum, the required elimination of heat from a closed circuit during the compression can involve a considerable increase in the temperature of the cooling water without any drawbacks resulting. In this way the quantity of cooling water is reduced from 10 to 20 per cent compared to steam plants. Furthermore, heating of the cooling water can be raised from 160 to 180 F, without alteration of the temperatures within the circuit. Thus the waste heat is given up at high temperature and can be utilized for heating purposes. It is particularly worthy of note that the entire quantity of waste heat can be made use of for heating purposes, without any modifications having to be made, as compared to operation without utilization of the waste heat. The final temperature of the cooling water can be raised to any desired level, for instance, by restricting the recuperation.

AK-Plant in Connection With Blast Furnace. In blast furnaces, coke ovens, oil fields, and refineries as well as in various branches of the chemical industry, large quantities of waste gas result from the processes employed.

Utilization of such surplus gases in open-cycle combustion turbines calls for compression of the gases to a pressure amounting to a few atmospheres, so that they can be burned in the combustion chamber which is under pressure. For this purpose the gases must be precooled and in the majority of cases also cleaned, i.e., all processes which involve considerable additional apparatus. In the case of a closed-cycle turbine the hot gases can be utilized just as they are, without preparation and compression of the fuel for the air heater, i.e., a possibility which increases the thermal over-all efficiency.

A closed-cycle turbine operated with blast-furnace gas can also be employed for direct drive of blast-furnace blowers. The

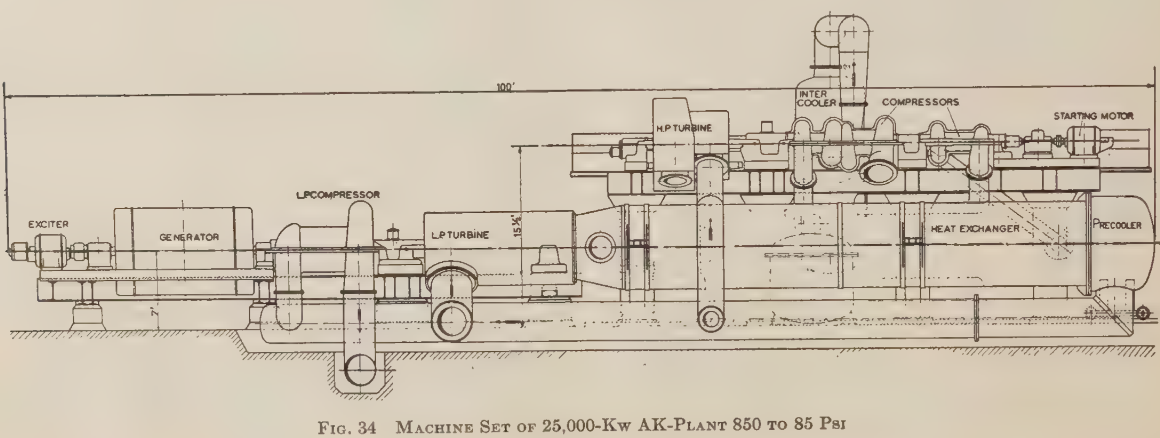

Fig. 34 Machine Set of 25,000-Kw AK-Plant 850 to 85 Psi

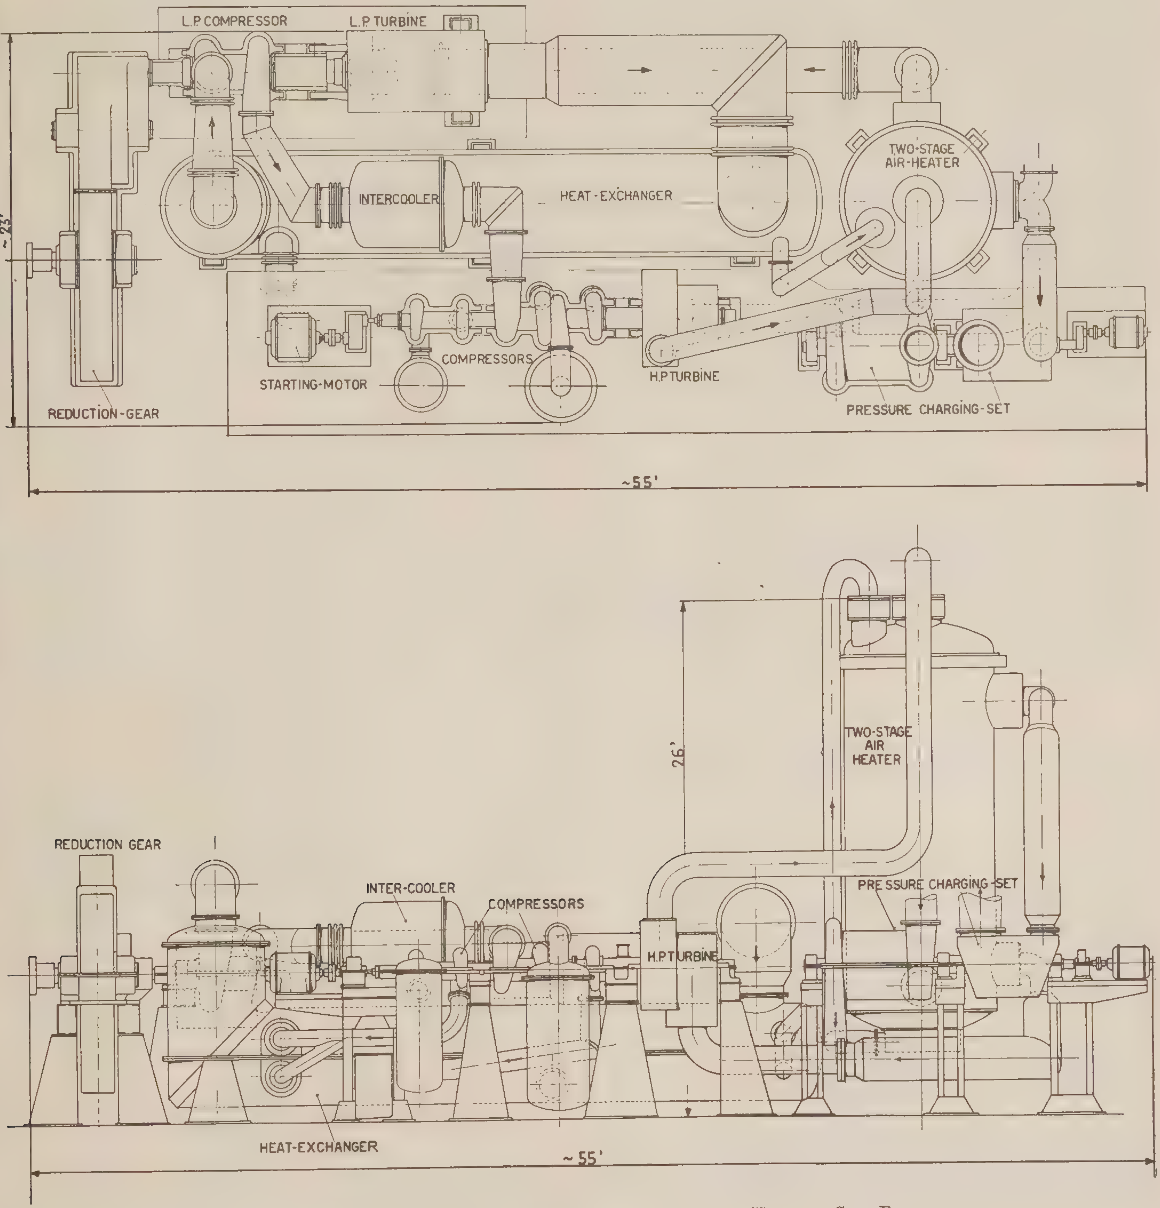

Fig. 35 Layout of a High-Efficiency 8000-Shp Closed-Cycle Unit for Ship Propulsion

arrangement of the turbine stages in conjunction with the compressor required for the circuit and the blast-furnace blowers, which must operate under widely differing speeds and loads, can be effected on similar lines to those already described in the preceding section concerning marine turbines. In this case also, the provision of two sets operating independently of one another may prove advantageous, since in this way a possibility is offered of attaining favorable thermal efficiencies over a large operating range, with regulation of the circuit density at different loads.

Another point to which brief reference may be made herein is that favorable combinations of blast furnaces, blast heaters, and air heaters for the power process can be realized for AK-plants. Particulars concerning such projects are to be found in a previous article (5).

Gas Generator and Fuel Producer. When coal is employed as fuel it may, according to its nature and quality, prove convenient to adopt gas generators in place of furnaces for producing the combustion gases for the air heater. In this connection, cleaning, cooling down, or compression are not necessary, such as are called for when an open cycle is adopted. The produced gas can be directly fired in an air heater.

Remarks Concerning Use of Light Gases in Closed Circuits

The following remarks concerning the advantages of employing other gases are the result of theoretical studies that have been

carried out by Professor Ackeret. He has compiled his calculations in the following form especially for the purposes of this paper:

For congruent entropy diagrams the efficiency of the closed-circuit process is independent of the nature of the gas. When assuming congruency, it is taken for granted that the relative pressure losses $\frac{\Delta T}{T}$ and temperature losses $\frac{\Delta p}{p}$ are the same on all heat-transmission surfaces. However, in spite of this, the adoption of other gases can prove advantageous because the output of the plant can be considerably increased at the same efficiency and with only slightly changed dimensions. To prove this more decisively let us assume that gases of the same atomic number, for example, only biatomic or only monoatomic gases be employed, the molecular weight m of which can be continually changed. For example, by a mixture of helium and argon, m could be continually increased from 4 to 40. For gases of the same atomic number the magnitudes

$$k = C_p/C_v \text{ and } \sigma = \frac{\eta \cdot g \cdot C_p}{\lambda}$$

are as is known independent from m.

We may observe the heat transmission at a given point of a tube having the diameter D which is traversed at said point by gases with velocity u, density ρ, pressure p, temperature T and viscosity η. Between the wall and the gas a difference in temperature $\Delta T = \theta$ shall prevail. The following equation then applies for the shear stress

$$\tau = C_f \frac{\rho}{2} u^2$$

and for the heat transmission per unit of surface according to Reynolds and Prandtl

$$g = \frac{C_f}{2P} \rho g C_p \cdot u \cdot \theta$$

in which for Reynolds numbers of medium size $\mathsf{R} = \frac{\rho u D}{\eta}$ the following may according to Blasius be inserted

$$C_f = \frac{0.0791}{\sqrt[4]{\mathsf{R}}}$$

The expression

$$P = 1 + \frac{1.7^4}{\mathsf{R}^{1/8}} (\sigma - 1)$$

is in small measure dependent only on R and is about 1. According to Eucken, σ is connected with k and may be expressed with considerable accuracy by

$$\sigma = \frac{4k}{gk - 5}$$

For a short tube section the following can immediately be ascertained

$$dp = -4C_f \frac{\rho}{2} u^2 \frac{dx}{D}$$

Congruence of the entropy diagrams, i.e., the same efficiencies, is realized when $\frac{dp}{p}$ and $\frac{dT}{T}$ are of equal magnitude for the different gases. Hereby, however, dx must be somewhat changed. In order to utilize the material equally well in all cases, let us further assume that at full load the pressures are also equally large. For gases the following equation generally applies

$$R = \frac{R}{m} \qquad \rho = \frac{p}{gRT} = \frac{pm}{gRT}$$

and in addition for gases of the same atomic number

$$C_p = \frac{p}{m}$$

Thus if we require for the same $\frac{dp}{p}$, it follows that

$$\frac{dp}{p} = -2C_f \frac{\rho}{p} u^2 \frac{dx}{D} = -2C_f \frac{u^2}{gRT} \frac{dx}{D} = -2C_f k M^2 \frac{dx}{D}$$

in which M is the Mach number $= M = \frac{u}{a}$ (a = velocity of sound). The same $\frac{dT}{T}$ leads to

$$\frac{dT}{T} = \frac{2c_f}{PT} \theta \frac{dx}{D} = \text{const}$$

in other words, $\frac{c_f \cdot dx}{P}$ or, since we can look upon P as being practically constant, $c_f \cdot dx$ = const for all m; but from the foregoing it follows that M = const.

Thus we have as a condition $\frac{u}{a}$ = const. But the velocity of sound

$$a = \sqrt{gkRT} = \sqrt{gk \frac{R}{m} \cdot T}$$

Consequently the flow velocity must increase with $\sqrt{\frac{1}{m}}$ if the same conditions of pressure and temperature are to be obtained.

For the element of length the following is obtained

$$\frac{dx}{D} = \frac{\frac{dp}{p}}{2c_f} \cdot \frac{1}{kM^2}$$

$\frac{dx}{D}$ is thus porportional to

$$\frac{1}{c_f} = \frac{\sqrt[4]{\frac{\rho u D}{\eta}}}{0.0791}$$

$$\frac{dx}{D} \sim \sqrt[4]{\frac{\rho u}{\eta}}$$

For the same temperatures the viscosity of gases having the same atomic number, with the one exception of hydrogen, differs only slightly (for the He-A mixture the viscosity varies between $m = 4$ and $m = 40$ only by about 10 per cent). Thus one can insert with sufficient accuracy $\frac{dx}{D}$ proportional to $\sqrt[4]{\rho \cdot u}$

From the foregoing we have

$$\frac{dx}{D} \sim \sqrt[4]{m \frac{1}{\sqrt{m}}} = \sqrt[8]{m}$$

i.e., only a rather small variation in the sense that for lighter gases the tubes become somewhat shorter. One sees immediately

where the advantage of light gases is to be found. The useful output of the machine is, namely, for the same tube diameter, proportional to $\rho u c_p$. It is also proportional to

$$m \frac{1}{\sqrt{m}} \cdot \frac{1}{m} = \frac{1}{\sqrt{m}}$$

Thus for lighter gases it will be considerably greater. Let us compare, for example, two gases, the molecular weights of which are as 1:9, then the velocity of flow adopted for the lighter gas must be 3 times greater; the output for the same efficiency becomes 3 times greater and the tube lengths for the heat exchanger are reduced by about 25 per cent. The weight of the charge of gas in the machine will increase somewhat more than m, becoming for this example less than $^1/_9$.

In physics the variation in the output can also be made clear in the following manner: According to Avogadro, the unit of volume for the same pressure and same temperature contains the same number of molecules, i.e., also just as many molecule degrees of freedom. Each molecule transports the same energy. However, since we are delivering 3 times the volume, it follows that 3 times the output will also be converted.

It is, however, known that in general light gases call for a larger number of stages (in the compressors and turbines). This is a drawback of light gases. In the case of the compressor, for example, the following equation obtains for the number of stages

$$n_k = \frac{2}{k-1} \frac{\ln \delta}{\psi M^2}, \quad \ln = \text{natural logarithm}$$

in which δ represents the adiabatic temperature ratio of the compressor, ψ the pressure coefficient. Thus in our case the law applies for the compressor (and also for the turbine) that n is proportional to $\frac{1}{M^2}$ in which M = peripheral velocity/sound velocity. Since $M \sim \sqrt{m}$ for the same peripheral speed, the number of stages would follow $1/m$, becoming, in the case of the example, 9 times greater. For the turbine there is little hope of deviating therefrom, but this does not apply to the compressor. Since the peripheral velocity of the axial impellers of the compressor does not reach the limit of their tensile strength, the peripheral velocity could, without impairing the efficiency by the Mach effect, be increased and the number of stages thus reduced.

As the weight of the machinery is relatively small in the case of a highly supercharged AK-plant, the increase in the number of stages could be accepted relatively easily, especially if it proves possible to employ radial impellers which can be operated up to the highest circumferential velocities without detrimental Mach effect.

For the heater tube the same heat-transmission coefficients as for water tubing are possible.

Comparative figures are given in Table 2 to facilitate understanding of the conditions. The comparisons relate to various gases and mixtures of gas with air.

As may be noted from the foregoing there are good prospects that further development work, especially in the case of installations for special purposes, will lead to higher efficiencies and reductions in the size of the plant. These remarks of Professor Ackeret confirm the author's opinion that the present development of the closed-cycle process by no means represents the ultimate attainable.

TABLE 2 COMPARISON OF DIFFERENT GASES FOR THE AK-PROCESS[a]

Gas	Air	He + CO_2	He + CO_2	He	H_2	
Mean molecular weight	29	8	6	4	2	
Specific heat, Btu/(lb)(deg F)	0.26	0.755	0.90	1.25	3.5	
Ratio of viscosity (T = const)	1	1	1	1	0.5	
Ratio of sound velocity	1	2.1	2.4	3	3.9	
Adiabatic pressure ratio for temperature ratio	4	2.92	2.71	2.52	3.65	
Volume, per cent CO_2 (1.45)	...	10	5	..	...	
Number of stages (ratio)	1	2.8	3.5	4.8	13.5	Constant circumferential velocity
Circumferential velocity	1	1.75	1.9	2.2	3.7	Constant number of stages
Diameter (ratio)	1	0.76	0.73	0.68	0.52	
Revolutions per min	1	2.30	2.6	3.3	7.1	
Heat exchanger						
Coefficient of heat transmission	1	1.86	2.12	2.56	4.35	
Number of tubes	1	0.66	0.62	0.56	0.27	(Ratio)
Length of tubes	1	0.82	0.76	0.70	0.85	
Surface area of tubes (weight)	1	0.54	0.47	0.30	0.23

Discussion

J. H. Anderson.[4] The author has made an excellent presentation of an outstanding achievement in engineering. Although time and further development will be required to determine whether the AK-system is to become an economic success, the author and his associates deserve only the highest praise for the ingenuity and perseverance required to turn this development into an engineering accomplishment of such obvious importance.

While this power plant could be compared to any prime mover, it seems most logical to compare it to a modern steam plant, for the simple reasons that both are externally fired and both can be built in large capacities. By the same logic, the open-cycle gas turbine most nearly compares with the Diesel power plant in its application and place in the economic structure.

It is, as the author has already pointed out, almost impossible to make an economic comparison between the AK-plant and a steam plant at the present stage of progress, but at the same time anyone will admit that this must be done eventually. With this in mind, it may be worth while to set down a few simple comparisons between the two types of plant.

Starting at the power unit, we have an air turbine in the AK-plant as compared with the steam turbine in the steam plant. Basically, the air turbine should be more efficient and cheaper for two reasons, i.e., there is no problem of handling liquids with attendant corrosion, and the volume ratio of expansion is far lower in the air turbine. Both of these considerations help to make a simpler and cheaper design possible, which should at least balance the problem of handling higher temperatures in the air turbine.

The air cooler and intercoolers in the AK-plant correspond to the steam condenser in the steam plant. Here the steam condenser is obviously much more expensive because more heat must be discharged at a much lower temperature difference. Also, the air-removal equipment and condensate pump are additional accessories required over and above those needed for the air coolers.

The compressor in the AK-plant corresponds to the boiler feed pump in the steam plant. Here the difference would appear to be in favor of the steam plant, although this must be subjected to thorough analysis.

The boiler, economizer, feedwater heaters, and superheater in the steam plant correspond to the air heater and recuperator in the AK-system. This is probably the largest question mark in a comparison of the two systems. In the air heater we have conditions roughly equivalent to those in the steam superheater. For this reason we have a higher average temperature difference to work with in the boiler. On the other hand, we have a lower heat input in the air heater. The recuperator is undoubtedly larger and more costly than the corresponding feedwater heaters. All in all, it is probable that the heaters in the AK-plant cost more than the corresponding heaters in the steam plant. Comments on this point by boiler manufacturers should be of great interest.

In the matter of auxiliaries, there would seem to be no question that the AK-plant is simpler and has less of them than the steam plant. This would be the case simply because in one case we have a liquid-gas plant, and in the other we have a pure gas plant.

Regardless of the present state of development, there can be no question but that the AK-plant is basically simpler to control than is the steam plant. Here again we have the simple reason that a gas is used throughout the system, instead of both a liquid and a gas.

It is difficult to make predictions on maintenance costs. However, it is probably safe to say that more machinery trouble is encountered from corrosion, wear, and solid deposits in any system where both liquid and gas are present than in a system where gas alone is present, and this is especially true in any system where variable temperatures are present. The problem of deposits on steam-turbine blades is a serious one which cannot be overlooked. While it is granted that the AK-system must operate with some higher metal temperatures than the steam system, it is probable that this will not cost as much in maintenance as other troubles in the steam plant.

It is perhaps foolish to pass judgment on the basis of the simple comparison here given, but even such a comparison should be enough to show that the AK-system deserves most

[4] Research Engineer, Ingersoll Rand Company, Phillipsburg, N. J. Mem. A.S.M.E.

careful consideration as an immediate competitor of the steam power plant.

The author has quite properly pointed out that the shaft seals are a critical component of this plant. This is obvious when one considers that there are probably 10 seals under high pressure. The ingenious method of using an oil seal at the lowest pressure in the system should make the seal losses roughly equivalent to those of an open-gas-turbine system. It would be interesting to learn what percentage of the losses was ascribed to the seals, and what clearances had to be maintained in the labyrinth packing to obtain this value of the losses.

The author has mentioned that the efficiency of an axial compressor dropped from 86 to 83 per cent during only 12 hr of operation in their shops. This does not seem to correspond fully with the experience of some others. For this reason it would be of value to have a further explanation as to how this drop in efficiency could be accounted for.

F. T. Hague.[5] The author's and Mr. Gygi's[6] visit to this country is both welcome and significant, in that it promises to focus increased attention on the study of gas-turbine power plants. The presentation of the paper, disclosing test results on a 2000-kw closed-type-cycle gas-turbine power plant, is evidence that the gas turbine for primary power generation is rapidly developing toward maturity.

It is becoming increasingly apparent that the complete gas-turbine power plant, which was a newcomer in this country 3 years ago, is making giant strides in being reduced to practice in several important lines of endeavor. Military releases have identified it as the fighting aircraft power plant of the future. Commercial interests view the prototype tests of propeller-drive gas turbines as a further boon to commercial aviation. In the locomotive field, powerful, compact gas-turbine power plants are currently being built. A high-efficiency open-cycle type of gas-turbine power plant has been demonstrated within the year, giving promise of application in fields of industrial power generation, and ship propulsion. The gas-turbine plant of which Escher Wyss has built a prototype, is the first reduction to practice of a design from which coal-burning central-station-type units of from 10 to 50,000-kw capacity may ultimately become a reality.

The author and his colleagues deserve high commendation for their engineering foresight in taking steps to reduce this type of gas-turbine power plant to practice several years before it was being given serious consideration elsewhere. It is only fitting to acknowledge that this foresight has given these engineers several years' time in which to study the theoretical and practical problems connected with this development. Their viewpoint on its ultimate accomplishment may well be more realistic than those who have been considering it for a shorter length of time. The fact that 98 per cent of Switzerland's power generation is water power presumably limited their combustion research with pulverized coal.

The proposed closed-cycle gas-turbine power plant is simple for engineers to understand who are already familiar with the open-cycle type of system. This closed-cycle system differs from open-cycle systems in one major respect; the physical size of the rotating and heat-exchange machinery is decreased as the system pressure is elevated. It is this characteristic of the closed cycle which makes it possible to build turbines and compressors for a 50,000-kw unit of smaller physical size than for a 5000-kw open-cycle unit. The closed-cycle type of system has its efficiency level affected in exactly the same manner as the open cycle with respect to any changes in maximum temperatures, compression ratio, intercooling, reheating or regeneration Like all good things, it is basically simple. This in no way detracts from the brilliance of the initial conception.

There are metallurgical limitations in the building of any high-temperature gas turbine. These are definitely less serious when the physical size of the parts is reduced. It may not be too much of an estimate to say that the metallurgical problems of a 25,000-kw closed-cycle plant will be comparable to those of a 5000-kw open-cycle plant. This is a favorable characteristic.

The practicability of the closed-cycle system may ultimately be determined by the problems associated with getting the heat from the fuel into the system. The author has elected to introduce the heat through an externally fired air heater, thus offering the possibility of using the cheapest grades of liquid fuels or pulverized coal. Such an air heater requires extensive use of high-priced stainless steel for temperatures above 1000 F. The precautions which must be taken to protect the tubes of such a gas-to-air heater from overheating, pose a difficult set of problems to the air-heater builder in designing an air heater comparable in both size and cost to a steam generator of equal plant capacity. Engineers interested in the development of a gas-turbine power plant will wait with interest to see how our air-heater manufacturers can meet these requirements at an economic cost when burning pulverized coal. Much, if not all, of the ultimate part that will be played by this cycle in primary power generation may well rest in the satisfactory solution of this air-heater problem when burning pulverized coal.

It is not to be expected that this and possibly other problems associated with this new form of gas-turbine power plant can be solved overnight. The problems involved in developing the steam cycle to its present level of performance and reliability required a long time for solution. We should, with equal consideration, concede that problems in connection with this new system which, at first glance, look to be formidable, may after further study actually yield to research and development. The engineering profession is learning to be optimistic regarding the possibilities of development of the gas turbine, and that optimism should be extended to studies of this new type of system.

M. L. Ireland, Jr.[7] The closed-cycle process at present appears to be the most practicable means to obtain single plant outputs in excess of about 6000 hp, and the author's company has shown unusual foresight in concentrating its efforts on this design.

For central-station applications this cycle offers the prospect of thermal efficiencies exceeding those now attainable with the most modern steam plants and this may well warrant the high development costs which must be incurred.

The prospect for closed-cycle marine gas-turbine power plants in excess of about 6000 hp appear to be less favorable for strictly commercial applications. Some idea of the initial cost and the operating and maintenance problems of such a plant can be gained from a comparison of the major components with the corresponding items of a steam-turbine plant for superheater conditions of 700 lb 850 F, as follows:

1 From the author's Fig. 35 we find that two air turbines are required which, though smaller in size, are probably more costly than the cross-compound steam-turbine unit because of the higher-temperature materials required.

2 Four air-circuit compressors and three intercoolers are required which correspond in function to the condensing and feed-water heating and pumping units of the steam plant. The cost of

[5] Assistant to Vice-President, Westinghouse Electric Corporation. Mem. A.S.M.E.

[6] Managing Director, Escher Wyss Engineering, Zurich, Switzerland.

[7] Engineering Technical Division, Newport News Shipbuilding and Dry Dock Co., Newport News, Va. Mem. A.S.M.E.

the compressors will probably more than offset the reduction in heat-exchange equipment, even when the increased circulating-water requirements of the steam plant are taken into account.

3 Even when pressure charging is employed, the air heater and regenerator when taken together appear to about equal the total heating surface, including air heaters of about 2 sq ft per hp, which is required for a steam plant of this size. Judging from the percentage of high-temperature materials required for the air heater, the cost will compare quite unfavorably.

4 The pressure-charging set for the air heater is understood to be necessary to reduce the dimensions of this unit, but this is felt to introduce undesirable complications for a marine unit which already contains so many novel features. In particular, it is believed that the pressure-fired boiler will be more sensitive to pressure and flow changes in the air circuit with consequent increased risk of damage to tubes subject to high thermal loading on the fuel-gas side.

5 There remain the high- and low-pressure accumulators, the control unit and the starting motor, which may be compared with the throttle and combustion-control elements of the steam plant.

When itemized in this way it is difficult to believe that the initial cost of the closed-cycle marine unit will compare at all favorably with a steam-turbine plant for, say, 700 psi 850 F at the superheater. The operating requirements appear to be quite similar, as in both cases primary control is applied to the weight flow of the working medium and the fuel control follows with a certain inevitable time lag. Considering the relative number of major rotating elements and the fact that combustion gases must pass over heat-exchanger tubes in both cases, there does not appear to be any evident advantage as regards maintenance.

The advantage in thermal efficiency over the conditions outlined for a steam plant is large, being approximately 15 per cent, but there remains a question, in this writer's mind at least, whether this will not be absorbed by increased capital charges and maintenance expense.

A substantial saving in weight is indicated which will be of importance for vessels carrying heavy cargoes. However, the fore-and-aft length of the closed-cycle unit in Figs. 35 and 36 is about 5 ft longer than the machinery compartment for a standard C-3 steam-turbine-driven cargo ship with 8500 shp. A considerable portion of the wing spaces abreast of the main plant will be required for generators, pumps, compressors and other ship's machinery and would be of little value for cargo space in any case. Therefore, in a cubic-capacity trade, the closed-cycle plant would probably be at a slight disadvantage.

In general it would appear that these factors can be considered only when a specific vessel and trade are under consideration and therefore should not be cited as intrinsic advantages or disadvantages of the closed-cycle plant as compared to a steam-turbine unit.

It is encouraging that the development of the controllable-pitch propeller has also been undertaken by the author's company and it is hoped that he will shed some light on one feature of this equipment which has given much cause for concern. During the process of reversing the propeller pitch it is necessary to move the blades back through the angle of zero lift, while the ship is still making headway. For a brief interval, while the blades are not fully reversed, they would appear to be receiving energy to drive the shaft which would result in an acceleration of the shaft speed. If the pitch control should become jammed in this position it would appear that dangerous overspeeding of the unit might occur. This situation would appear to be more critical for a gas-turbine plant than with Diesel engines which are believed to be the type of power plant to which the controllable-pitch propeller has so far been mainly applied.

Joseph Kaye.[8] This paper presenting a statement of the status of the closed-cycle gas-turbine power plant, brings to mind some interesting questions which it does not answer directly. (*a*) Does the closed-cycle gas-turbine plant possess any marked improvement in efficiency in comparison with other power plants of a similar nature, such as a steam power plant? (*b*) Is the size of the closed-cycle gas-turbine plant smaller than that of a comparable steam plant?

The closed-cycle gas turbine might also be compared with the more widely known combustion-gas turbine in regard to fuel consumption and size. However, such a comparison would be inconclusive at best, since different fuels are used at present for the two plants, and since the primary functions of the two plants are not similar. It should be noted that the closed-cycle gas turbine and the steam plant utilize the same fuels, perform the same primary functions, and possess parallel component parts.

For purposes of comparison, the following two power plants may be selected:

(*a*) The proposed closed-cycle gas turbine, shown in Fig. 10 of the paper, involves four compressors with three intercoolers, two turbines with two heaters, and a regenerator with an assumed effectiveness of 90 per cent. In addition a precooler is necessary at the entrance to the first compressor. The inlet temperature of each turbine is 1200 F, and from the data given in Fig. 10 the turbine efficiency is about 93 per cent and the compressor efficiency is about 90 per cent.

(*b*) The second power unit is the customary condensing steam power plant with one reheater present. For the purpose of this comparison the temperatures and pressures at each turbine inlet are taken as those in Fig. 10 of the paper. The condenser is assumed to operate at 1 in. Hg, and the feedwater pump to have an efficiency of 90 per cent. Regenerative feedwater heaters are omitted for simplicity; their effect on efficiency can be easily estimated from known data. The pressure drops in the boiler, superheater, and reheater are equal to the corresponding pressure drops in the high-pressure side of the regenerator, first heater, and second heater, respectively, as given in Fig. 10.

The efficiency of the proposed closed-cycle gas turbine in (*a*) is about 39 per cent allowing for external losses.

The efficiency of the steam power plant in (*b*) is about 38 per cent for turbine efficiencies of 93 per cent, and is about 35 per cent for turbine efficiencies of 85 per cent, allowing in each case for external losses. These efficiencies could be increased by 10 per cent through the introduction of several regenerative feedwater heaters. The efficiency could also be increased somewhat by the readjustment of the pressure ratios for the two turbines to yield the maximum steam cycle efficiency for the same temperatures.

On the basis of efficiency, the proposed closed-cycle gas turbine in (*a*) represents no marked improvement over the comparable steam plant in (*b*).

The power units in (*a*) and (*b*) may be compared on the basis of size. Consider first the turbines and compressors of (*a*) and the turbines and feed pump of (*b*). The turbines of (*a*) must deliver several times the power of the turbines in (*b*) for the same net power of the complete unit, since the power consumption of the feed pump in the steam unit in (*b*) is negligible compared to the power required to drive the compressors of the gas-turbine unit in (*a*). In other words, for a net power of 2000 hp, the turbines in the steam plant in (*b*) will deliver slightly more than 2000 hp, whereas the turbines of the unit in (*a*) must deliver about 4000 hp, and the compressors will absorb about 2000 hp. Even if the specific weight of the turbines in (*a*) is less than that for the turbines in the steam unit in (*b*), it is apparent that the steam

[8] Assistant Professor of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Mass. Jun. A.S.M.E.

plant has a decided advantage with respect to size of its prime movers.

Consider next the size of the heat-transfer units of the closed-cycle gas turbine in (*a*) and of the steam plant in (*b*). Both units have a heater in which heat is transferred to the working fluid at high temperatures. Both units have a cooler for rejecting heat from the working fluid; in the case of unit (*a*), this cooler comprises the precooler and intercoolers, while for unit (*b*), it is the condenser. Moreover, the gas turbine in (*a*) has an additional piece of heat-transfer equipment, the regenerator.

For equal heat flows and similar constructional details, the size of the heaters and of the coolers will be determined mainly by the major resistances to heat transfer. Under these conditions the size of the heater of the gas turbine in (*a*) will be larger than that of the steam plant in (*b*) for several reasons: The thermal resistance of the high-pressure gas of the heater in (*a*) will be larger than the resistance of the high-pressure vaporizing fluid in the steam plant in (*b*). Then, the use of high-pressure combustion to reduce the thermal resistance on the flue-gas side of the heater is applicable to the steam power unit in (*b*) as well as to the gas turbine in (*a*). For equal heat flows and similar constructional details the combined size of the precooler and intercoolers of the gas turbine in (*a*) will be larger than the size of the condenser of the steam unit in (*b*). These heat-transfer units use water as the cooling agent, and they will have about the same thermal resistance on the cooling-water side. However, the thermal resistance of the low-pressure gas in (*a*) will be considerably greater than the resistance of the condensing steam in (*b*).

In conclusion, if the large size of the regenerator of the closed-cycle gas turbine in (*a*) is considered, it is apparent that the over-all size of the equipment for the closed-cycle gas turbine in (*a*) will be greater than the size of the steam plant in (*b*) without a compensating gain in efficiency.

ALF LYSHOLM.[9] In the writer's opinion the high thermal efficiency is to a great extent due to the perfect aerodynamic design, especially of turbine and compressors, as well as to the high-efficiency 90 per cent regenerator, which has counterbalanced the inherent unavoidable losses of the closed cycle. These losses are as follows:

1 Losses in the externally fired air heater.

2 Aftercooler losses, including the loss caused by a higher inlet-air temperature of the first compressor, as compared to the open cycle. In cases where the cooling-water temperature is lower than the air temperature a precooler could be used with advantage for the open cycle.

3 "Feed"-pump losses.

The author states that the inlet volume for the open cycle is many times higher than that of the steam-turbine cycle. That is correct for an open simple gas-turbine cycle, but not for the reheat intercool cycle using the same or somewhat lower maximum pressure than that of the closed cycle.

In Table 3 of this discussion a comparison is given of the inlet volume of different gas-turbine cycles, as well as steam cycles, taking the author's data for the 8000-shp unit as a basis.

The table shows that the inlet volume of the open cycle, using the same maximum pressure as the AK-cycle, is only about 20 per cent higher than the combustion air volume of a steam-turbine plant operating at maximum load. As higher velocities in the ducts may be used for a gas turbine, the ducts will be of about the same dimensions as those of the steam plant.

Compared with the closed cycle the efficiency of the multiple-reheat-intercool cycle will be considerably higher, amounting to 10 to 15 per cent for the example just given. On account of the low air rate this combination is ideal for very large gas turbines.

As regards coal-firing, it should be noted that the open cycle also may be fitted with an external air heater if that should be required. In this case the additional heat losses due to combustion air amount to only a few per cent, as hot air from the gas-turbine exhaust may be used as combustion air in a "tail-end" boiler.

TABLE 3 COMPARISON OF VARIOUS GAS-TURBINE CYCLES[a]

Cycle	Air pressure, psi	Pressure ratio	Air rate, lb per hphr	Compressor-air-inlet volume, cfm	Combustion-air-inlet volume, cfm	Thermal efficiency, per cent
AK-double heat.....	600/60	10	33	15000	14000	33
Reheat intercool, 4-3-0.85..............	600/14.7	41	18	31000	.....	38
Reheat intercool, 3-2-0.85..............	250/14.7	17	24	41000	.....	37
Steam maximum load	14.7	..	..	.....	26000	17
Steam, normal load..	14.7	..	..	.....	19000	23

[a] The data in this table have been computed with a turbine efficiency of 88 per cent, and a compressor efficiency of 83 per cent.

FREDERICK NETTEL.[10] The author mentions that the double-isotherm cycle (in which we recognize the Ericsson cycle) is in its theoretical form equivalent to the Carnot cycle, and seems to claim on this basis some sort of superiority for it. It must be kept in mind that the approach to the Carnot cycle is realized by assuming not only ideal compression and expansion, but also 100 per cent recuperation.

Under the same assumption, however, even the simple Brayton cycle approaches Carnot efficiency as the pressure ratio decreases. For thermodynamical purposes Fig. 3 can be interpreted as agglomeration of three Brayton cycles.

Any basic superiority of the double-isotherm cycle appears doubtful from this viewpoint, apart from quite fundamental additional considerations which enter the question as soon as even slight deviations from 100 per cent efficiencies are contemplated for compression, expansion and recuperation.

On the basis of fundamental thermodynamic research (the results of which are not yet released) it must be said that it is even doubtful whether any of the two cycles is particularly suited to approach Carnot efficiency with a minimum of heat-transfer surfaces, and in particular it must be doubted whether the intentional complete omission of any adiabatic compression is always helpful. Let us consider only the last stage of an isothermal compression. There we carry away compression heat by cooling, only to replace it immediately thereafter by heating. This is all right as long as the heating is obtained, so to speak, free of charge by 100 per cent recuperation, but if we have only 90 or 80, or 70 per cent recuperation it is sheer waste of heat. This is only one of the reasons why the Ericsson cycle is not the ideal to

[9] Consulting Engineer, Stockholm, Sweden.

[10] Consulting Engineer, Manhasset, Long Island, N. Y.

strive for in practical plants. Approaching a cycle which is best under ideal conditions does not give the plant that is best under conditions prevailing in practice, namely, with finite efficiencies of the components.

The interrelations between the method of intercooling, reheating, and recuperation, if applied simultaneously, are much more complex than it would appear from the presentation of the AK cycle, and that is the reason why the writer arrives at appreciably different results in setting up optimum conditions for open as well as closed cycles.

The author speaks of the supercharged closed cycle as "an important new feature" and mentions as its "chief characteristic" the changing of the density of the working fluid in accordance with the load to be furnished. Without wishing in the least to detract from the fact that Ackeret and Keller have introduced this principle for air "turbines," we must face history by mentioning that the closed cycle and density regulation were actually anticipated for air "engines" decades ago. However, this is not the place to go into details, and that does not change the fact that the application of this principle in a properly modified form has outstanding promise for high-power air turbines. In commenting on the merits of the AK cycle, its demerits and limitations need also to be given due consideration.

The utilization of coal as fuel is imperative if the gas or air turbine is ever to play an important role as a prime mover. The author points to the radical decrease in the size of heat exchangers and the favorable heat transfer to highly compressed air. He touches on the necessity to preheat the combustion air in the air heater furnace.[11] Since the stack gases from the furnace and the combustion air have to exchange heat near atmospheric pressure, this air heater does not profit in any way from the supercharging of the power cycle, and the necessary heat-transfer surface will be of the same magnitude as that of air heaters used in steam boilers. We know that those air heaters have surfaces which often are multiples of the boiler heating surfaces proper, and we know too that they determine the furnace efficiency, not only in steam power plants, but equally in air-turbine power plants of the AK-type. However, this is not necessarily the case in other closed or semi-closed plants of a modified layout and hook-up.

With reference to the section of the paper on operating cycles of the AK process: Two intermediate coolers and a pressure ratio of about 3 to 4 are mentioned as the most favorable for the simplest air-turbine plants. The author does not give any basis for this statement. Actually the best pressure ratio varies widely with recuperator effectiveness, top temperature at turbine inlet, turbine and compressor efficiencies, etc.

In practice an "oversize" heat exchanger can be made to cover up nearly any deviation from optimum layout, and this is what appears to have been done in the 2000-kw experimental AK plant, where a recuperator of close to 90 per cent effectiveness is being used. While a recuperator of 75 per cent effectiveness is already pretty large, one of almost 90 per cent is definitely oversize.

Now the author may reply that his recuperator is as such much smaller than those required in open gas-turbine plants due to the much better heat transfer resulting from supercharging. However, this would be beside the point if it can be shown that an equal or better efficiency can be reached in a similar plant of modified layout with smaller transfer surfaces; and that can be shown.

Actually, in a similar manner as indicated by Soderberg-Smith for open cycles, the optimum pressure ratios increase with increasing refinements (intercooling and reheating) but fall with rising effectiveness of the recuperator, and there is no short cut to fixing a ratio at 3 to 4 as "most favorable."

All Sankey diagrams show high furnace efficiencies obtained by air preheaters for the combustion air, but the text gives no indication of their size and the degree of air preheat.

In view of the foregoing, it is difficult to understand Fig. 9 fully. In the "Index of Figures" (referring to Fig. 9) a minor error (due probably to translation) has crept in. Only a small Δt_A = 18 deg F in combination with a large ϵ_B = 10 per cent can lead to the same curve 2 as a larger Δt_B = 36 deg F in combination with a smaller ϵ_A = 5 per cent. The same holds good for curve 3.

With reference to air heaters: Under this section the influence of preheated combustion air is stated "to lead to an increase in the furnace temperature," and that in plants burning pulverized coal "such preheating of the secondary air is desirable," since it permits a reduction in the size of the combustion chamber.

Every reason for favoring air preheating given is sound, but the most important fact, namely, that the AK plant would badly disappoint in efficiency without such a very large air preheater, may escape notice as the author proposes "not to deal further herein with the details of coal-fired air heaters."

There can be little doubt that supercharging of the air heater on the gas side has great merits for marine plants. However, the problem of regulation of the supercharging set and the problem of very low loads, for example in naval plants, is one of the most complicated that awaits solution. Probably the author did not go into these details as outside the scope of a general paper. It is in any case necessary for us to realize that supercharging of air heaters in closed or semiclosed air-turbine plants deserves closest attention in the future.

Do the figures 1.5 to 3 sq ft of heat-transfer surface per kw include the air preheaters for the combustion air?

Governing: The size of the air accumulators for a 50,000-kw plant would be interesting to know if we consider the possible tripping of the generator circuit breaker twice or three times within, say, $^1/_2$ hr.

The writer will conclude with some remarks regarding the efficiency curves in Fig. 7. According to the author, without altering the temperatures the efficiency of the plant should be almost equally high at part loads as at full load.

The curves, while comparing very well indeed with those of other prime movers, will necessarily show a steady drop with the load. The reason is simple enough; if at full load the tube material in the air heater is thermally fully utilized, a certain safe limiting wall temperature is reached. At lower loads the air density drops and with it the heat transfer from wall to air, and if we try now to maintain the top heating temperature the wall temperature would rise beyond a safe limit. Since that is inadmissible, a lowering of the top temperature becomes imperative, resulting in a somewhat lower efficiency.

While curve (*a*) is shown as a horizontal, this would seem attainable only if at full load the tube material would not be thermally fully utilized, thus admitting higher wall temperatures at partial loads. Whether or not a plant should be designed in this way will depend primarily on the load diversity factor of the plant during operation.

J. K. Salisbury.[12] After one has mastered the prerequisite elements of engineering, the problem of design of power-generating equipment becomes primarily one of economics. It is well recognized that any power plant consists primarily of a means for supplying heat to a system, and an accompanying means for rejecting less heat than is supplied. The difference between the

[11] Without, however, mentioning the conditions under which this must be done.

[12] Turbine Generator Engineering Division, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

heat supplied and the heat rejected is equal to the power generated, according to the fundamental laws of thermodynamics. In many cases the supplying of heat to a system and the rejection of heat from a system requires the use of indirect heat-transfer surfaces. Both the weight and the quality, as well as the degree of fabrication of the materials which go into these heat-transfer surfaces determine to a large extent the cost of the power-generating system.

Typical exceptions to the generalization that power plants require heat-transfer surfaces are the open-cycle gas turbine and the Diesel engine. In these plants heat-transfer surface is not required because the heat generated within the working fluid is transferred by direct contact, thus eliminating an expensive type of surface, which must be suitable for operation at high temperatures, for high efficiency. Both of these power plants reject heat to the atmosphere through the medium of the exhaust gases. In the case of the Diesel engine, an appreciable portion is also rejected to the cooling water. Obviously, both of these plants thus eliminate a large item of expense.

Consider the general proposition of the transfer of heat through an indirect heating surface in the type of power plant which requires it. According to the well-known equation of heat transfer, the heat transferred Q, is given by the expression

$$Q = UA\Delta T$$

The last two factors in this equation represent material for interesting speculation. By increasing the value of A we can decrease the value of ΔT, with constant heat input Q. When we increase the surface area A, we increase the cost of the power plant; at the same time we reduce the value of the temperature difference ΔT; according to the second law of thermodynamics this improves the efficiency of the power plant. It is readily apparent that we may exchange cost of the power plant for efficiency of the power plant; when the cost increases the efficiency improves, when the cost decreases the efficiency becomes poorer. This principle is particularly apparent to any student of gas-turbine cycles, although it is also applicable to steam power plants.

The first factor in the heat-transfer equation, the heat-transfer coefficient U, is ordinarily not considered to be susceptible of much improvement. However, the author has, in the design of the plant described in the paper, indicated a method whereby U may be increased without appreciable direct cost. By increase of the pressure level in the system the heat-transfer coefficient is increased almost in direct proportion, thus reducing the value of A required for a given rating and efficiency. In other words, the use of the pressure cycle in which heat-transfer surfaces in regenerators are reduced by the use of high pressure on both sides of the surface, is considered to be of importance in the gas-turbine field. This principle permits realization of high efficiency without the usual accompanying high cost of the regenerator.

The engineering of the plant described in the paper indicates an acute awareness of the factors which are effective in yielding a high-efficiency power plant. The engineering of this plant cannot be questioned because in the first place the power plant has successfully performed, and in the second place the plant has produced a high efficiency. The author and the Escher Wyss Company are to be sincerely congratulated on their achievement. The advantages of this plant, in order of importance, seem to the writer to be as follows:

1 Control of output by variation of density, thus maintaining constant internal efficiency. (It is obvious that there is no inherent advantage in efficiency at a given load due to the use of the pressure cycle.)

2 The probable ability of the plant to burn coal.

3 The reduction in heating-surface cost per kilowatt.

4 The use of clean air in the circuit, avoiding decrease of compressor and turbine efficiency with use, and justifying the use of a larger regenerator.

5 The possibility of building units in larger ratings.

Although the engineering of this plant cannot be questioned, the economic situation does appear to be open to question, especially in the United States. It is recognized that any gas-turbine plant is handicapped by the requirement of a compressor rated at about $^2/_3$ of the total gross power output of the turbine. Thus the sum of the ratings of the compressor and turbine in nearly any gas-turbine plant is equal to about 4 or 5 times the net output. Intrinsically therefore the gas-turbine power plant uses machinery which, on the basis of its rating, should cost several times that of the turbine in a steam plant of the same rating. In the open-cycle gas-turbine plant this higher cost is partially offset by the elimination of expensive heat-transfer surface such as the boiler.

The closed-cycle plant suffers the same disadvantage, with respect to the cost of the rotating machinery, as the open-cycle plant and, in addition, requires the use of expensive indirect heat-transfer surface in the air heater. In the writer's opinion it is highly questionable whether this air heater, or one of similar capabilities, could be built in the United States for less than $75 per kw of plant rating. This price, when added to the higher price of the rotating machinery and regenerating equipment, would seem to make the total cost of a power plant of this type considerably higher than the usual price for steam power plants in the United States. The apparently higher fixed charges on such a plant would mitigate against its economic application in either industrial or central station plants, particularly the former, where the fixed charges are usually taken to be a higher percentage than in the central-station industry.

Even with the higher fixed charges, which in our judgment would obtain, such a plant might be acceptable, especially where the fuel cost is high, if it were impossible to build a plant with this efficiency in any other manner. Our studies, however, indicate that with equal ease a 2000-kw steam plant can be designed having an efficiency equal to that of the Escher Wyss closed-cycle plant. Such a steam plant would be designed for a somewhat higher pressure than the experimental plant operated in Switzerland, but for a lower temperature, to compensate for the higher pressure; the material requirements would be no more stringent than in the author's plant. The inlet steam conditions would be 600 psig 1200 F, and the exhaust pressure 0.66 in. Hg.

This exhaust pressure, according to our estimate, could be obtained with the temperature of the cooling water used in the Escher Wyss test plant. Using a turbine efficiency which includes some margin, a good feedwater-heating cycle, 5 per cent auxiliary power, and 92 per cent dry-boiler efficiency (equivalent to about 86 per cent on the usual basis), the thermal efficiency of the steam plant was found to be 30.4 per cent. While on first thought the superheating of steam to 1200 F seems to be difficult of accomplishment, it must be realized that in this country steam superheaters have already been built with an outlet temperature of 1400 F, for special applications. Furthermore, the quantity of heat which must be put into the superheated steam at high temperature, for a unit of energy output at the generator terminals, is considerably less, as will be shown.

The degree of severity of the metallurgical problems in the respective plants is described quite clearly by a statement of the relative quantity of heat put into the working fluid between given temperature limits, per unit of net energy output. One interesting way in which this may be done is to express the energy in-

put in units of kilowatt-hours, in order to make this energy directly comparable with the output of the generator. Since modern metallurgy does not recognize temperatures below 900 F as a problem, these temperatures will not be considered. In Table 4 of this discussion is included a mercury-steam plant, in which a mercury-vapor cycle is superposed on the 600-psig 1200 F steam cycle. While the writer's company is not prepared to build such a plant today, it is of academic interest in that it indicates the considerably smaller quantity of heat supplied at high temperatures in this cycle, despite the very high thermal efficiency of the plant.

TABLE 4 COMPARISON OF QUANTITY OF HEAT SUPPLIED AT VARIOUS TEMPERATURES PER UNIT ENERGY OUTPUT

(Kwhr of heat supplied per kwhr at generator terminals)

Temperature range, deg F	Escher-Wyss aerodynamic turbine plant	600 psig − 1200 F steam plant	500 psig − 1200 F mercury superposed on 600 psig −1200 F steam plant
900–1000	0.578	0.131	0.119
1000–1100	0.584	0.132	0.119
1100–1200	0.590	0.131	1.464
1200–1268	0.405	0	0
Total, above 900	2.16	0.394	1.70
Plant thermal efficiency, per cent	30.5	30.4	37.8

This table is of great interest because it indicates that in a steam plant, designed for the stated steam conditions, only about $^{1}/_{5}$ as much heat per net kilowatt of output is required to be transferred at temperatures above 900 F. Even in the mercury-steam plant, which has a thermal efficiency considerably better than that of the closed-cycle plant, the heat transferred at temperatures above 900 F is considerably less, although admittedly a large proportion of the heat is transferred at 1200 F. This heat transfer, however, occurs from gas to boiling liquid, so that the metal temperatures approximate the boiling-liquid temperatures.

The writer would like to ask the author several detailed questions. In view of the fact that the average steam plant has a total heating surface in the boiler and the condenser of about 2 to 2.5 sq ft per kw of plant rating, what is the corresponding figure for the Escher Wyss plant, including regenerator, air heater, combustion-air heater, intercoolers, and precooler? Since, according to previously published information, the combined pressure drop on the high-pressure side of both the regenerator and air heater of the test plant was only 3.5 psi, how is this reconciled with the 10 to 15 psi pressure drop mentioned by the author for the air heater only? Published figures indicate that the recirculating-fan power in the test plant was only 2 kw, or 0.1 per cent of the net plant output. American experience in this connection has indicated that recirculating-fan powers are usually very much higher than this percentage. Will the author undertake an explanation of how such low fan power was achieved? Calculations by the writer indicate that the mechanical efficiency of the rotating machinery, based on the net generator output, is approximately 86 per cent. Even when all of the mechanical losses in the turbines are charged against the sum of the powers of both the turbines and compressors, the mechanical efficiency is only 97.4 per cent, a rather low value. Will the author state whether this low value is due to the oil seal used on the shaft ends or whether there is some other reason for the high losses?

Author's Closure

General. It is not an easy matter for the author to answer the many questions posed in the long discussions of this paper in as exhaustive a manner as he would like to do. The principal reason for this is the fact that this new system of gas turbines is actually still at the beginning of its practical development. Therefore, not all of the elements have found their final form. The field of application is very large and, always considering the principle of the high-density circuit, many solutions are possible. It is impossible to give definite and general answers, for example, for the best layout or for prices. They may vary widely with given conditions, such as cooling-water temperature or supply, air temperature, efficiencies asked for, necessary weight, etc.

A crew of engineers has worked for more than 10 years and not under favorable conditions, on this project to bring it to its present state, namely, actual installations in industrial plants. The deeper we went into details in our studies, the more we found, not only from the technical and physical but also from the economical point of view, that the closed-cycle power unit offers many operating advantages as well as higher efficiency, as compared with steam turbines and open-cycle combustion gas turbines in many applications, especially for ship propulsion and stationary plants.

It is an honor and a pleasure for us to see what great interest has been created by our visit to America, and in the discussion with many famous scientists and engineers. These discussions developed many new and helpful ideas for us and we derived some very useful data, especially from the metallurgists. All this encourages us to an optimistic outlook regarding broader realization of our objectives. We are much impressed and thankful for the open-minded criticism.

Before answering the several items of discussion in detail, the author would like to make a few general remarks which hold for many questions and allusions common to different discussers. It will be recalled that this conference was meant to give a general survey of what has been accomplished by the author's company during the war and to explain the physical base of the cycle. Naturally, we have constantly kept in mind the matter of economics for future plants. We know much more about costs now than we knew a year ago, as a consequence of relief in prices for different materials involved. Even at the present time, a closed-cycle plant of, say, 12,000 or 25,000 kw output with oil and gas firing does not cost much more than a modern steam plant, if one takes into account all the saving in space for the building, the foundations, the lack of feedwater preparation, etc.

In contradistinction to steam-turbine practice, the whole range of output from, say, 6000 to 50,000 kw can be covered by a few types of machines and apparatus only. Many elements, such as blades, tube bundles of heat-exchangers, headers, or air heaters, then auxiliaries as leakage compressors, regulating gear, etc., can more easily be simplified, classified, and normalized. This will help considerably in achieving low-cost fabrication methods, and therefore in lowering further the cost of a plant.

An oil-fired plant of about 17,000 hp net output is under construction now at the Escher Wyss Works in Zurich. It is hoped that, in the near future, much more can be said about prices, operating experience, and maintenance, based on facts. The overall efficiency, including all auxiliaries, of about 37 per cent at full load must also be considered when comparing prices and economy with other systems.

The author would like to point out that the construction of the test plant of 2000 kw at our works, which is dealt with extensively in the paper was started more than 10 years ago. This was really meant for development and research work and not as representative of later plants. All direct comparisons with other caloric plants concerning results achieved are therefore misleading. It may be of interest that in the same space which we used for the test plant, at the present state of technical development, we can install a 15,000 to 20,0000-hp plant. This shows that many simplifications and savings in construction based on the long experience and studies have been achieved.

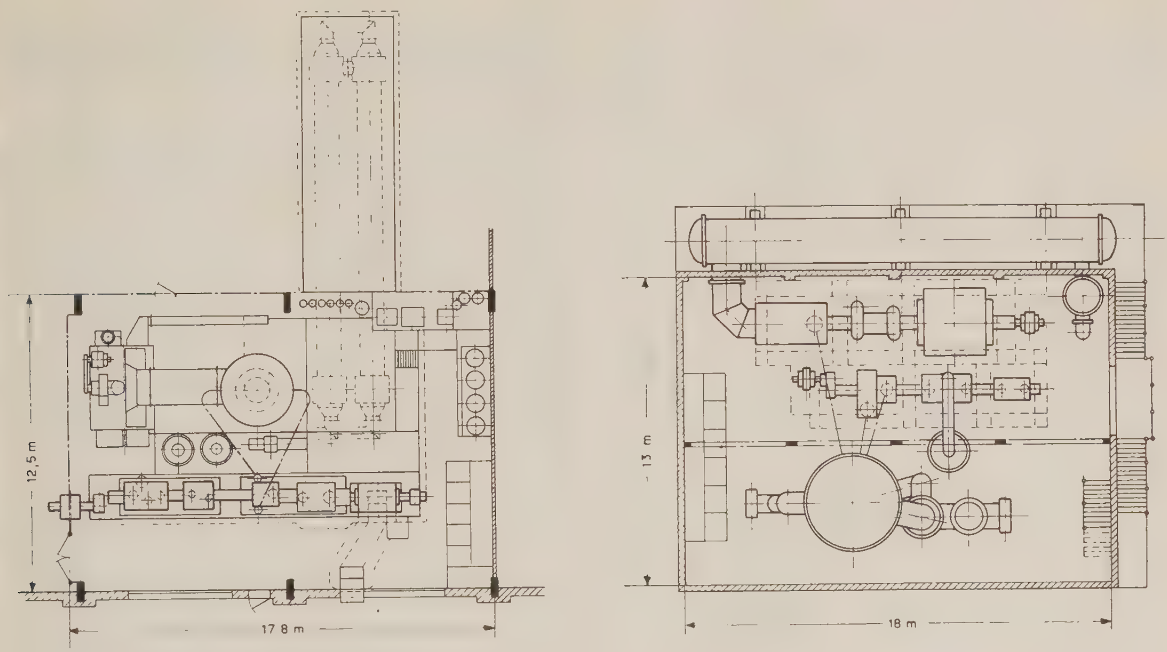

FIG. 36 SHOWS AREA COVERED BY TEST PLANT (LEFT) AND THE FIRST INDUSTRIAL APPLICATION (RIGHT) NOW UNDER WAY
(Test plant, 2000 kw; plant under construction, 12,500 kw.)

Fig. 36 of this closure shows the area covered by the test plant with which many American engineers are familiar, as well as the first industrial application now under way.[13] The saving is due mainly to the large output, and the choice of the higher pressure of 50 atm abs with a pressure ratio of about 10 between the low- and high-pressure sides because two-stage expansion is used.

All necessary details of this plant will be divulged to the engineering profession when it is finished. Therefore, the author begs the reader's indulgence for not going into detail here. However, it may be said that we are not only optimistic about the technical progress achieved but also concerning prices, as a result of the reasons given herein. In this respect, it must not be forgotten that the amount of special and expensive materials for the machines is small because the dimensions are small, as compared with other gas turbines.

On our last visit to America and England, it was gratifying to learn that the necessary tubes for the air heater can be produced on a normal commercial basis. They are similar to the type widely used for modern cracking plants under more severe conditions than occur in the AK heater. The total weight of heat-resisting material, compared with the total iron weight of the whole installation, amounts to only about 12 to 15 per cent. To give an idea; the cost of the air-heater tubes for a big plant amounts only to about 7 per cent of the total cost. These figures show that the supercharged cycle, because of its smaller machine dimensions and heat-exchanger surfaces, offers advantages generally not anticipated.

Reply to J. H. Anderson. The principal points concerning matters of cost have been dealt with in the foregoing general statement. In comparison with corresponding steam plants the better possibilities to normalize elements and to build standard plants will play a big role in the future and affect costs. As the air heater from the construction point of view is a simpler apparatus than a steam boiler, especially when supercharged-firing is used, there is no reason why this apparatus should cost more than a modern high-grade boiler.

The control and regulating system of the plant by varying the density only leads to valveless machines and apparatus in the cycle itself. The whole regulating block is a separate unit outside the cycle in cold atmosphere. This arrangement gives favorable operating conditions and much lower costs than the regulating device of modern high-pressure high-temperature steam turbines.

We have tried different shaft-seal constructions in the test plant. We now use the same liquid-seal method which has been widely used in our compressors for poisonous and dangerous chemical gases where shafts must be absolutely tight. As a consequence of the different alterations we have made in the test plant, the leakage loss has been relatively high. As the official report by Professor Quiby[14] on the trials shows, the compensation for air leakage amounts to about 30 kw at full load (2000 kw). The percentage loss in a new plant will be less.

The drop in efficiency of 3 per cent at a certain test compressor in a rather short time has been measured in different instances. It is believed that such losses depend naturally upon the individual form of guide vanes and runner blades. The difference in these friction losses in different airfoil-bladed machines may be due to the different Reynolds number involved. If a test is made with low velocities, the effect is naturally not so obvious as at high Reynolds number, where, as modern research on friction on plain and curved surfaces shows, the relative roughness plays a much bigger role.

Reply to F. T. Hague. It was very encouraging for us to have the opinion of an engineer who has dealt with many pioneer

[13] A brief description of the entire project is given under the title, "New Developments in Gas Turbine and Boiler-Plant Practice," *Power*, vol. 90, Aug., 1946; details of the Escher Wyss installations are given on pp. 88–90, of this article.

[14] Reprinted in *Oil Engine*, November, 1945.

efforts in the fields of steam and gas turbines and who has successfully carried new ideas on to realization. We can assure him that what seems to have occurred to him, when first studying our project, occurred to us also in the course of its development. Many details appeared to be formidable at first glance but our team of engineers has always found technical solutions. Construction of all elements has been based upon intensive research work in our laboratories. As we cannot accomplish all our objectives at the same time, we first have concentrated on the construction of oil- and gas-fired installations. For this purpose, we have arrived at simple arrangements for the air heater. The coal-fired air heater will be the next step to be achieved, based on actual studies and experiments. We are quite optimistic about this field too.

The principal problem in the case of pulverized-coal firing is the necessity for keeping slag and ash particles as far as possible away from the innermost rows of tubes near the combustion center. This can be effected by blowing in the recirculated flue gases, which serve for reducing the temperature of the furnace, along the whole inner tube wall between the tubes themselves. Tests which have been carried out in this connection show that this is already possible even in the case of small circulating volumes.

Since circulating gases at approximately 1000 F are relatively cold, the blown-in current has the additional action of bringing about quick cooling and granulation of the slag particles.

As Mr. Hague looks favorably and optimistically to the possibilities of the closed cycle, the author also would like to tell him that we think this system may also have a future application in connection with atomic power.

Reference has already been made to the advantages of employing light gases as the working medium for special purposes. For instance, helium or helium mixtures permit of heat-transmission values being attained which are of the same magnitude as for water. Thus, for otherwise similar conditions, the heating surfaces in a helium heater could again be considerably reduced compared to the air heater.

In so far as conditions can be foreseen, the closed helium circuit would prove suitable in a thermal power plant employing atomic energy. Since helium is neutral to the material of the pile and in addition has advantageous characteristics from the viewpoint of nuclear-physics in that, like graphite, it acts as a neutron moderator, the pile could be brought in direct contact with the gas. The pile might, in fact, possibly be arranged in a pressure vessel. The helium issuing from the compressor of the circuit could be supplied to the pile under a high pressure of 700 to 1400 psi, for increasing the heat-transmission figures and reducing the dimensions, and would afterward flow in direct contact as a cooling medium around the uranium rods, as also through bores in the graphite itself. In this way the pile would give up the heat which it produces by direct convection to the helium. It may be foreseen that under the assumptions mentioned (increased pressures) the large quantities of heat produced in the pile will, on account of the good heat transmission, be capable of being usefully taken up. In this manner no tubes would be required at all for the helium heater. Calculations show that if we assume a pile temperature of 1500 F as admissible, only a very small surface is needed to heat up the circulating helium to 1300 F.

For 1000 kw net output of the plant, about 15 to 20 sq ft in direct contact with the gas are sufficient without a greater total pressure loss than 3 to 4 per cent in the "pile heater." Therefore, a 50,000-kw plant would need only a heat-transfer surface of less than 1000 sq ft. Whether such dimensions are possible from the physical aspects is not yet known.

The adoption of a uranium pile in place of a combustion chamber would in the case of an open-circuit turbine be detrimentally affected by the fact that only small heat-transmission values are attainable with air. Furthermore, the nitrogen would absorb neutrons and the open air current continually deliver radioactive products to the atmosphere. Moreover, there would be the danger of the graphite in the pile being burned by the oxygen in the air.

The use of steam as working medium likewise has the drawback of a considerable absorption of neutrons and of a small heat transmission in the superheated condition, also requiring complicated installations.

It is also possible to combine a normal closed cycle working with air or another suitable gas with a "pile"-heater through an intermediate circuit bringing the heat from the pile to a heat exchanger (air heater with tubes). This intermediate circuit is closed too and would contain compressed helium in order to get high heat-transfer coefficients both in the pile and in the air heater. By this arrangement the working circuit with the machines is entirely separated and safe from radioactive particles. Calculations show that the necessary surface for the helium air heater amount only to about 200 plus 300 sq ft per 1000 kw when working with pressures of 60 to 80 ata.

We appreciate that the problems of utilizing the plant in conjunction with atomic energy are as yet unsolved and cannot yet be foreseen fully, particularly with regard to the construction. Nevertheless, the foregoing remarks show that the closed circuit has by no means reached the end of its development. On the contrary, this new principle opens up wide possibilities for the improved conversion of heat into mechanical energy.

Reply to M. L. Ireland, Jun. The method of estimating costs of future plants and the author's point of view upon that subject are discussed in the introduction to this closure. In connection with point 4, it may be said that all our recent studies show that pressurizing is very suitable for marine applications with oil-firing and also for gas-fired heaters in stationary plants. The control of the small charging set is not complicated.

The author agrees fully with the discusser's advice that only in specific cases can the different systems be reasonably compared.

We have made some studies for ship propulsion in the meantime and especially on the regulating problems in connection with variable-pitch propellers. Some of these problems were discussed by Dr. Salzmann, Chief Engineer of Research Laboratories of Escher Wyss, at the Detroit meeting of the A.S.M.E. in June, 1946. As a result of these studies, it may be said that we do not foresee any particular difficulties in regulating and stabilizing in connection with turboelectric drive or in combination with variable-pitch propellers.

For ships the closed air cycle offers an important advantage over the steam plant because of its ability to fit into given spaces as no gravity is acting on the working medium. All apparatus and machines can be arranged in a great variety of ways. The fact that the amount of air to be taken in for the closed-cycle air heater is the same as that of a Diesel engine or steam plant gives the same dimensions of inlet openings and outlet openings for the combustion gases. The combustion gas turbine needs many times more surface for these purposes.

Reply to Joseph Kaye. Our projects show that a closed-cycle power plant needs less total room than a corresponding steam plant of the same output. To give an idea; a 25,000-kw stationary plant can be built in a space of 90 × 52 × 40 ft for oil or gasfiring. In this space all the auxiliaries, all the accumulators, and all the heaters and regenerators of the machines are situated. The weight will be about 35 to 40 lb per kw. Under favorable conditions, we can guarantee an efficiency at the coupling of the output turbine of 37 per cent at full load, 35 per cent at half load, and even 27 per cent at 20 per cent load, all auxiliaries included; this with a working temperature of about 1200 F. Higher temperatures of 1300 F or more, we believe, can be real-

ized in the very near future, after having gathered experience with the first plant. The figures cited can be attained by modern steam plants only for large outputs and with rather complicated installations.

Reply to Alf Lysholm. It is true that we use high-efficiency regenerators in the closed-cycle system and that we need, like all other turbine systems, highly efficient compressors and turbines. But just to realize high figures constantly the absolutely pure medium offers ideal possibilities in the supercharged cycle. The Reynolds numbers are very high and heat transfer is good. The simple open-cycle combustion gas turbine uses a great excess of air to cool down the combustion gases to allowable temperatures for the turbines. This cannot be changed. The closed cycle needs about the same amount of intake air as a Diesel or steam plant.

Concerning the reheat-intercool cycle mentioned for open gas turbines but with high pressures, the author is not familiar with the possibility of its practical realization. The high pressure ratio of about 40, involved in this system, will require other constructions in machines. It is also thought that the different reheat stages would lead to constructional complications. More reheat stages or intercooler stages could also be introduced in the closed cycle as already pointed out in the paper. Yet the theoretical gain of efficiency would, in our opinion, be balanced by additional mechanical pressure and temperature losses.

Reply to Frederick Nettel. We try to follow the theoretical double isothermal cycle as closely as possible because we think this is a suitable way for gas processes to approach the maximum possible efficiency between given temperature limits with simple technical means which, from the engineering, constructional, and metallurgical point of view, are available today and in the near future. Mr. Nettel mentions another approach to the best thermal output, but as he does not give further explanation, the author cannot very well discuss the possibilities. It may be that there are other schemes for gas turbines but we shall stick to the one idea explained. All the deductions concerning best pressure ratios, reheat factor in heat exchangers, etc., should be regarded only in connection with the double isothermal cycle. For other cycles there are naturally, as Mr. Nettel points out, other most favorable relations. We arrived at these relations, for example, of 3–4 for the best pressure ratio with direct expansion and 10–12 for double expansion, not only from the theoretical calculations of the cycle but also taking in account all the losses of pressure and temperature involved in practical plants. Also, the quantity of circulating gases for a given output plays an important role.

The supercharging of the air-heater furnace not only lowers the surface of its tubes but also the surface of the combustion-air preheaters, because a part of the heat of the combustion gases is used in the expansion turbine which drives the supercharging set.

Concerning the size of the heat exchanger, it may be said that 75 per cent effectiveness is too low to get high efficiencies with normal circuit temperatures of about 1200 to 1300 F; 90 per cent effectiveness is really the figure upon which our actual construction is based. This corresponds to temperature differences of 45 to 65 deg F in this apparatus between the two air streams. It is an important item of the closed cycle that this high effectiveness can be realized with comparatively small surface and in small space; the heat-transfer in coefficients is many times higher than in an open-cycle installation, and we have to deal with an absolutely pure medium, so that we can really choose small diameters of tubes without any danger of scaling. As Mr. Nettel does not explain how he will attain better efficiencies and with what means, the author can only explain here the reasons which led us to our design.

All indications of air preheat are given in Table 2 of Quiby's official report.[15] As Mr. Nettel explains, an error crept in the explanation of Fig. 9 of the paper. It should be read as explained in his discussion.

Our studies on supercharged air heaters led us to the opinion that the charging set is not so complicated an arrangement as perhaps it seems at first glance. All the regulating is established automatically to a great extent.

The figure of 1.5 sq ft of heat-transfer surface per kilowatt relates to the air-heater surface plus preheater for a supercharged heater set. The air-preheater surface is dictated by the point of view of economy and is different in ships from that in stationary plants.

The size of the accumulators depends upon the chosen pressure of the cold-storage air, and upon the "time-table" of the plant. The load variation, Mr. Nettel admits, is communically severe. To give an idea we would need about 100,000 cu ft.

Reply to J. K. Salisbury. We were much interested to have Mr. Salisbury's opinion of our work. As we know, he is in every respect an expert in the gas-turbine field. We would like to thank him again for the compliments he paid to the engineering work of our team. The author was gratified to have had several conversations with him on this subject, and the principal advantages of the plants he mentions in his discussion are just those which convinced us since the start of our work to stick to it through all de-development difficulties. In connection with Mr. Salisbury's survey of the economics of the situation, for the reasons explained in the introduction to this closure, the author can only agree with him that it is an open question. Naturally, the author is not too familiar with conditions in the United States. For the markets he knows better, he is not at all doubtful about cost development.

The air heater with pressure firing is much less expensive than Mr. Salisbury estimates. The costs for the whole plant are even less than 75 dollars per kw.

The comparison of a 2000-kw modern steam plant which can be buil according to Mr. Salisbury's proposition, with the first 2000-kw closed-cycle test plant is not too favorable for the closed-cycle system. As explained in the introduction, one must not forget that the test plant was meant for other purposes than for industrial service and that it is a 10-year-old design. An up-to-date new design would naturally give much better values. Apart from that, at the present time we do not intend to build plants with such small outputs, because in this respect the author agrees fully with Mr. Salisbury: We think it would not pay. The advantages of the closed cycle are much more pronounced for plant ratings, say, above 5000 kw.

The last detailed questions of Mr. Salisbury can be answered as follows:

Surfaces. Our actual design is based on a total surface, including heater, regenerator, combustion-air heater preheater of about 4 to 5 sq ft per kw. These figures may change in the future with other designs. About 20 per cent relates to the air heater, 20 per cent to the preheater and coolers, and 60 per cent to the regenerator. Naturally, this changes the whole aspect.

Pressure Drop. The absolute pressure drop depends upon the pressure level used; 10 to 15 psi result with a maximum pressure of ~800 psi in modern design. The smaller value belongs to the air heater of the test plant.

Circulating Fan. In operation of the test heater, we only needed a very small amount of recirculated gas to cool and protect the tubes, and the furnace, as a consequence of the layout. The secondary air of combustion, led in a suitable way along the lower end of the temperature. In new air heaters the construction will be somewhat different and a bigger fan will be used.

Mechanical Losses. As Prof. Quiby pointed out in his report,[15] these losses were higher than usual because of the special arrange-

ment of the machine group and bearings. At least 1.5 per cent total efficiency could have been won with other design. The oil seals play only a minor role in the mechanical losses. But one must not forget that the mechanical losses, as derived from the tests also include the internal leakage losses of working air. Therefore, an exact figure for the mechanical losses cannot be calculated. Naturally, the rather high value is not inherent in the closed-cycle system and can be kept normal in other plants.

The Influence of Viscosity on Centrifugal-Pump Performance

By ARTHUR T. IPPEN,[1] CAMBRIDGE, MASS.

The wide use of centrifugal pumps in the oil industry demands that their performance characteristics for oil be predicted with reasonable assurance. A systematic study of performance changes with increasing viscosities had not been undertaken so far under controlled laboratory conditions. For the purpose of undertaking such a study theoretically and experimentally, the Hydraulic Laboratory of Lehigh University and the Cameron Pump Division of the Ingersoll-Rand Company co-operated in following through a comprehensive program of research at Lehigh University during 1944 and 1945. Over 200 performance tests for viscosities up to 10,000 SSU were completed on four variants of centrifugal pumps, employing a special test stand designed and built under war conditions.

The influence of viscosity changes on the head, discharge, and input-power characteristics of the pumps is demonstrated graphically and systematically for a wide range of viscosities and speeds. The usefulness of a special Reynolds number for pumps is demonstrated and test results are correlated on that basis. General conclusions are possible as to the influence of various features of design, since several pumps of different specific speeds were tested. A theoretical analysis establishes definitely the variables to be considered and places the discussion for the problem on a sound scientific basis, especially with regard to disk and ring losses.

Introduction

The influence of viscosity on the performance of centrifugal pumps has not received, up to the present, the systematic attention of the pump engineers which this problem deserves in view of the ever-increasing use of the centrifugal pump for the transport of viscous liquids. A first pioneer effort, and so far the most extensive one, was made by Professor Daugherty (1)[2] about 20 years ago. Various papers (2, 3) have appeared since then, but they were never based on more than a relatively small number of field tests carried out by various investigators with greatly differing pumps. These tests were used to derive correction curves for efficiency by extensive extrapolation of the test information on hand and must clearly be recognized as a temporary means of considering the viscosity influence.

In recognition of the need of a systematic approach to this problem under controlled conditions, the Hydraulic Laboratory of Lehigh University and the Ingersoll-Rand Company of Phillipsburg, New Jersey, entered into a co-operative agreement to explore the behavior of centrifugal pumps when pumping oils. A special test stand was designed and constructed under wartime restrictions and over two hundred performance runs were made during 1944–1945 on four variants of centrifugal pumps with viscosities ranging up to 10,000 SSU. The influence of viscosity changes on the head, capacity, and input-power characteristics was systematically explored for each variant of pump and for several speeds. The usefulness of the Reynolds number for the presentation of these characteristics was demonstrated convincingly and all results are correlated on that basis. The data presented in the diagrams are those obtained in the present investigation only. No attempt was made to include information from other sources, since it was almost always found lacking in completeness. This situation is analogous to that existing for many years in the field of pipe friction, until finally the pertinent variables were definitely established and a final solution found.

It is to be hoped that the experiments reported here will bring forth many detailed experimental results in complete form from the files of various investigators, so that the conclusions drawn from this work may be either confirmed or be modified to fit into a more general picture. However, it is felt that the paper represents the first attempt to analyze the test results on the basis of all pertinent variables so that individual influences can be isolated more easily. Thus their share in the over-all effect of the viscosity on the performance of centrifugal pumps is to be recognized in relatively true proportions.

It may be mentioned that the paper had to be severely limited in presenting the information on hand. The descriptive part on the experiments had to be cut more than may be desirable from the viewpoint of clarity in order to include the fundamental results of greatest value to the engineer concerned with this problem. The same limitations had to be imposed on the theoretical part which covers only those aspects which are most useful and characteristic in explaining the results of the experiments as stated in graphical form.

EXPERIMENTAL PART

General Outline of Test Program

The stated purpose of the experimental study was to find, if possible, a specific relationship between viscosity on one hand and efficiency, head, capacity, and power input on the other hand. The results for four different variants of pumps were to be correlated. The choice of pumps was naturally restricted by the power supply of the hydraulic laboratory, by the range of the torsion-dynamometer, and by the available storage space for the oils used in the tests.

(a) *Specifications of Pumps Tested.* Under the circumstances the four pumps listed in Table 1 were chosen as most suitable and as of widest possible use in the pumping of highly viscous oils. All vital dimensions and normal-performance data for water are listed in Tables 1 and 2. Pump No. 1 was a single-stage, single-suction pump which could be fitted with hydraulically identical impellers of the closed and open type. This pump was relatively small and of low specific speed. The pump No. 2 was a single-stage double-suction pump which could be run with impellers of different diameter. Thus the specific speed was varied to a value of almost 3000 with a small impeller, however, not without some sacrifice in efficiency. The experiments covered, consequently, a range of specific speeds between 1000 and 3000 which is the range of most efficient operation for radial-flow pumps.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.

(*b*) *Properties of Liquids Employed.* The program of testing contemplated originally the use of water and of two oils as experimental liquids. For the latter the range of viscosities was defined by the range of temperatures seasonably obtainable, i.e., from almost normal outside temperature upward to a maximum produced by dissipating the power input. No special heating or cooling equipment was provided. The variation in the volume circulated was sufficient to obtain the desired range of temperatures and viscosities. Two black oils, giving a medium slope in the viscosity-temperature chart, were selected and are referred to subsequently as heavy oil (HO) and light oil (LO). A third oil was added, however, after the LO-runs were taken, since it appeared desirable to bridge the gap between the viscosity of water and that of the light oil.

This so-called thin oil (TO) was produced by mixing the light oil with a certain amount of fuel oil. The light oil proved to be extremely stable and its viscosity remained constant for almost half a year of intermittent testing. The thin oil and the heavy oil were affected somewhat by the pump testing and frequent analyses were made to adjust results for changes in viscosity whenever they exceeded the limits of permissible errors. Fig. 1 presents the essential data on viscosities and specific gravities for these oils.

(*c*) *Schedule of Testing Program.* The experiments started by determining the performance of each impeller of the two pumps for water. All impellers were tested as summarized in Table 2 for three different speeds with the exception of the largest impeller, which was run only for the two lower speeds, since the torque for the high speed exceeded the dynamometer capacity. The water tests checked very closely the performance of the pumps reported from the Ingersoll-Rand laboratory and served in addition the purpose of establishing working procedures and of finding out about the general performance of the test stand. After some minor alterations were completed, the four sets of runs

were repeated for the light oil, covering usually the possible range of viscosities on the same day for any one speed. It was preferred to change the pumps and impellers rather than the liquids, thus avoiding contamination of one oil by the other, which would have become appreciable during the course of the testing program. The light oil was then cut by the addition of fuel oil to a lower viscosity and the four sets of runs were again repeated for this so-called thin oil. Finally the heavy oil was turned into the lines and the process was repeated a fourth time.

Thus two pumps with two impellers, as described in Table 1, were tested for four different liquids and for three different speeds. Six performance runs were taken for each oil in the average, so that the total number of tests exceeded 220.

Experimental Equipment

The experimental equipment was largely assembled under the restrictions of the wartime economy and therefore contains whatever could be made to serve on the test stand, from the material resources of the two co-operating agencies. The result of the planning on this basis, however, was adequate in every respect for the proper execution of the testing program.

(*a*) The general arrangement of the circulating system is shown in Fig. 2. Six 750-gallon tanks formed the basic storage units for two different oils. A triangular arrangement of three tanks each in two stories was decided to be the most compact and practical one with respect to piping and housing. When the pipes were filled with one oil, two additional tanks contained the same oil on two levels with the upper tank in the rear always empty and ready to be used as a volumetric-measuring tank. The upper tanks could be drained very fast by gravity into the lower tanks. The entire system of pipes and tanks may easily be analyzed from the isometric views in Fig. 2. The meter calibration circuit and the pump testing circuit are shown separately and are outlined by heavy lines. All tanks were open, however, all pipe ends were submerged considerably below the oil level, so that entrained air never posed any problem.

All the circulating was done by the test pumps driven by means of a torsion dynamometer, as illustrated in Figs. 3 and 4. The driving arrangement of the dynamometer was a system of pulleys and a 65-horsepower induction motor, which was powered from a special transformer set with 3-phase, 60-cycle, 220-volt alternating current. Automatic voltage regulation was provided in the 4400-volt main feeder line of the University, so that serious speed variations were never encountered during tests.

(*b*) *Measuring Equipment.* Pump discharges had to be metered over a wide range and three liquid meters shown in Fig. 5 were installed, therefore, in separate lines of 8 in., 6 in. and 4 in. diameter. Orifice meters were used for the 8 in. and 6 in. lines and a 4 × 2 in. Venturi happened to be available for the 4 in. line. The meter approaches were at least twenty-two diameters in length and the valves in the approach lines were only used in wide-open or completely closed position. The operation of the meters therefore was satisfactory at all times. All discharge regulation was done by means of valves at the end of the circuit, so that the entire system was normally under positive pressure. The orifice meter of 4.92 in. orifice diameter in the 8-in. line was used almost exclusively for the large pump and the 4 × 2-in. Venturi meter was adequate for the small pump, so that the 6 × 3.60-in. orifice was rarely used. The orifice plates were made of $^3/_8$-in. brass plates with a square edge of $^1/_{16}$ in. and a downstream bevel of 45 deg. The pressure connections were located one pipe diameter upstream and one-half pipe diameter downstream.

The temperatures of the liquids were checked at three points by means of standard thermowells and dial-type indicating thermometers. The latter were mercury-actuated and furnished

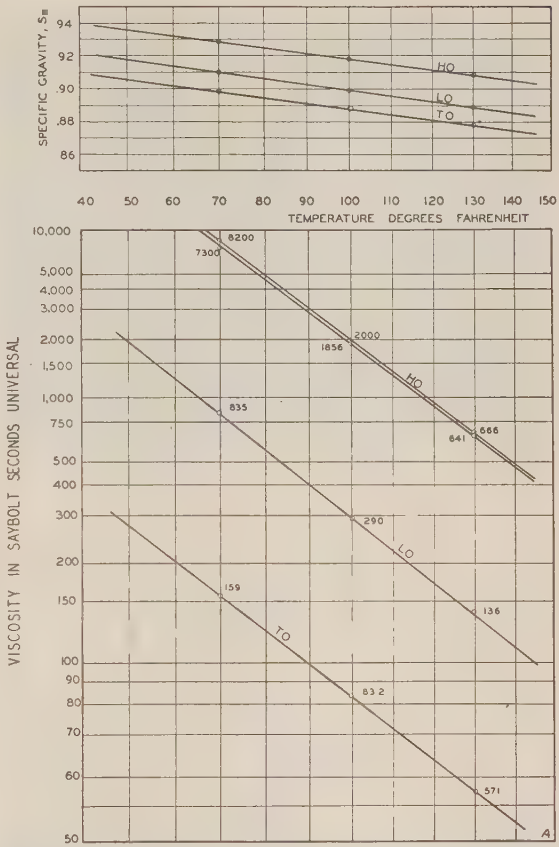

Fig. 1 Properties of Oils

with temperature-compensated capillary tubes. Readings to the nearest half degree Fahrenheit were deemed sufficient. The first well was located in the suction line of the pump about 4 ft upstream, the second was in the manifold immediately below the discharge line connection, and the third recorded the temperature of the liquid below the meters.

For visual checks, on the discharge and suction pressures, two Bourdon-type gages were included on the instrument board shown in Fig. 6; however, all discharge and suction heads used in the analysis were obtained from mercury-water manometers. The mercury manometer connected to the discharge side consisted of two differential gages connected in series, each of 6 ft length. A range of 50 psi could thus be covered without a balancing pressure. If the low pressure end of the manometer was placed under a 25 or 50-psi counterpressure, the range was extended to 100 psi. In the end the mercury gages arranged so as to require a minimum of corrections, saved considerable time since calibrations were unnecessary. The oil in the connecting lines was prevented from entering the water-mercury gages by means of large pots filled with oil in the upper half and water in the lower. The oil-water level in the pots was observed by means of glass gages and was checked and adjusted before every run. The same arrangement was used for the differential manometer connected to the liquid meters. Due to the relatively small differences in specific gravity of the oil and water, small changes of the oil-water level in the separating pots will not

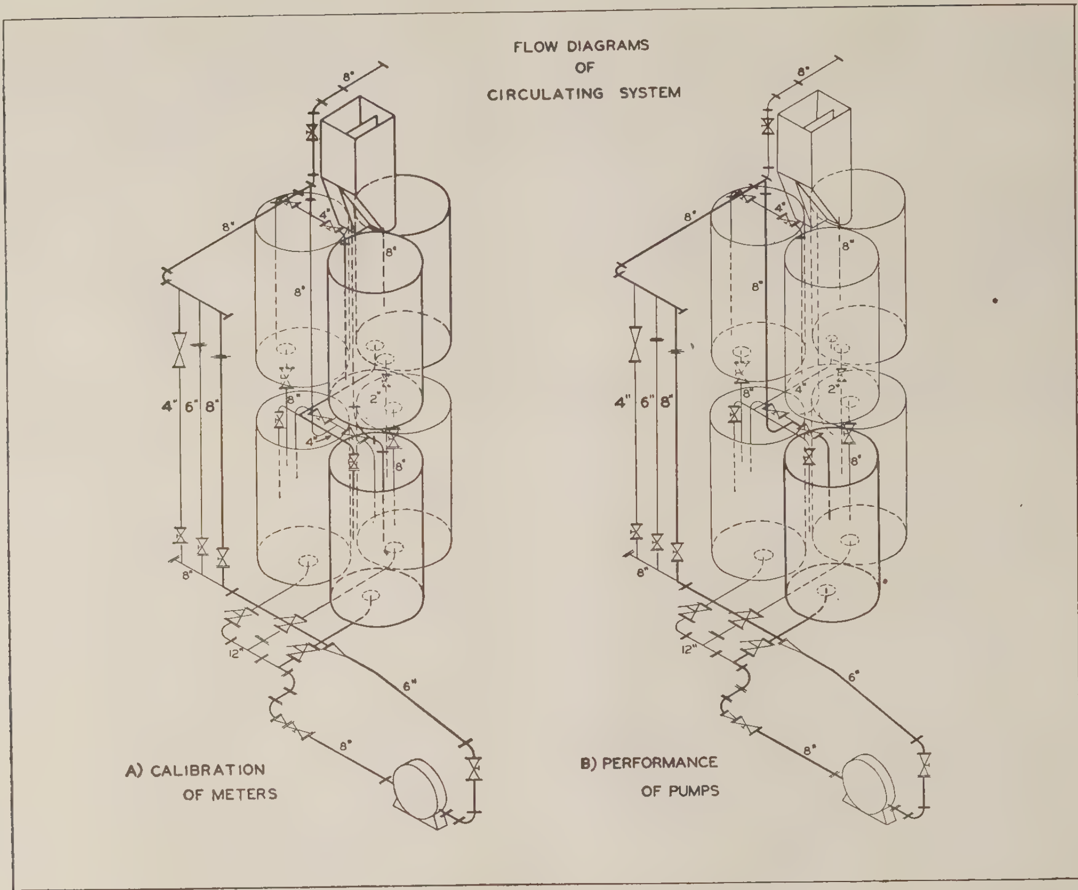

Fig. 2 Line Diagram of Circulating System

affect the readings. The speed was measured with a Chrono-Tachometer and with a revolution counter electrically operated for $^1/_{10}$-minute intervals. It was read for every test point and comparisons were made with a Hassler Tachometer with results well within the precision of either instrument. The tachometer and revolution counter are connected to a synchronous motor powered from a generator mounted on the pump shaft.

Experimental Procedures

(*a*) *Calibrations of Measuring Equipment.* All the instruments used were subjected to several calibrations during the experimental period. The mercury gages of course do not need special calibration, except that the Bourdon gage tester was checked against the mercury columns. All connecting lines were freed of air and particularly the discharge gage was checked before and after each run for air, by the use of a special water-air manometer, the latter indicating easily any errors of 0.01 ft of water column. Balance was always required within this limit and was always obtained.

The dynamometer bars were calibrated by careful static load tests and showed a constant torque per unit deflection over the entire range. Naturally the percentage of error of the reading for any run was dependent upon the torque range covered for any particular pump and speed.

The speed measurements were checked against simultaneous measurements taken with other tachometers and were found to be consistent within one fifth of one per cent, which was within the required limits.

The temperatures indicated by the dial thermometers were verified by the use of a mercury thermometer certified by the Bureau of Standards. The readings were also checked during runs by mercury thermometers in adjacent thermowells, which had been compared to the standard thermometers. Sticking of the dial hands was prevented by lightly tapping the glass cover.

The main problem in ascertaining the fundamental quantities for the performance of the pumps was encountered with the liquid meters. While the circulating system for calibrating purposes is indicated in Fig. 2, some of the phases of the calibrating runs merit mentioning. Noticeable temperature differences in the oil circulated had to be avoided. Therefore the oil was normally discharged from the line into the upper storage tank and from here by gravity back into the lower tank. The flow was then gradually switched over to the swing spout, thus taking the oil in the upper storage tank out of circulation. As soon as steady-flow conditions were established again through the meter, the flow was deflected into the measuring tank, while a constant level was maintained in the lower storage tank by admitting oil from the upper storage tank. This procedure naturally required considerable practice but worked out very satisfactorily. The results of the meter calibrations are given in Fig. 7 and are stated in a form which deviates somewhat from the orthodox way. The discharge coefficient C_D for the 4 × 2-in. Venturi meter is

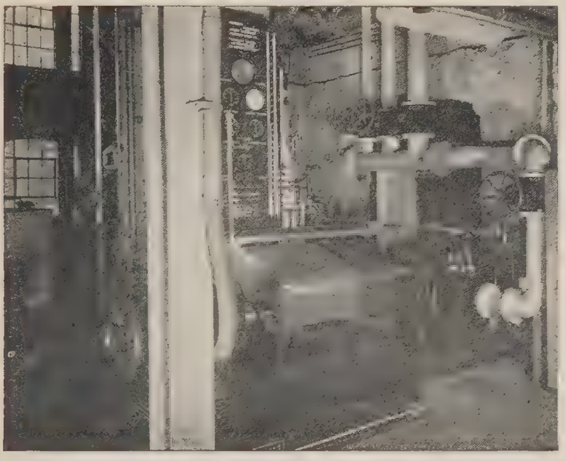

Fig. 3 General View of Test Setup

Fig. 4 Pulley System and Dynamometer

plotted against the Reynolds number for the 4-in-diameter pipe divided by the discharge coefficient C_D. Similarly the results for the 8 × 4.92-in. orifice meter are given in terms of a correction coefficient for viscosity K_m plotted against the pipe Reynolds number for the 8-in. pipe divided by the discharge coefficient. This latter quantity can be calculated directly from the differential-manometer readings and the correction coefficient K_m is thus obtained without trial and error. The discharge coefficient for water C_D, as introduced, is equal to 0.6185. The Venturi meter curve is compared to the curve given in the Fluid Meter Report of the A.S.M.E. and is seen to lie considerably below this curve. It is shown extending down to an experimental value of $C_D = 0.50$. The orifice curve is compared to Johanson's curve for a similar orifice in a 1-in-diameter glass tube and shows remarkable agreement. It may even be argued that the discrepancy is due to the slight difference in the orifice - pipe diameter ratio, which was 0.615 here, while Johanson's curve holds for 0.595.

(b) *Typical Performance Tests.* Most operational difficulties were discovered and ironed out by running first a full series of experiments with water. Only minor improvements, however, were necessary, and definite procedures for the oil runs were formulated. The dimensionless performance curves shown in Fig. 8 are those obtained for the medium-specific-speed impeller IL 22 and they are typical of the range covered by individual tests. The almost complete absence of viscous effects for the normal range of operation with water was indicated by all water runs, proving, if it be necessary indeed, that the Reynolds numbers normally encountered with water are in the so-called "rough-flow" zone.

All performance runs with oil were carried out by recording all pertinent instrument readings photographically by means of a 35-mm Kodak camera. Thus readings for individual points were taken speedily and simultaneously for permanent reference. Runs of ten to fifteen test points were normally completed within ten minutes, which fact considerably diminished the increase in temperature during any run. Upon termination of one run the pump was operated near normal discharge and was run continuously, until the dissipation of power had resulted in bringing the temperature to the desired higher value. The experimental procedure was then repeated. The temperature of the oil could be varied for any of the higher speeds from about 70 to 125 deg by continuous running within one day. Thus five to eight performance runs were obtained within a four- to eight-hour period. Shutoff conditions were usually tested by closing down fairly fast from a large discharge, thus retaining a fairly normal temperature of the oil churned in the pump. At best, however, the shutoff points are only approximate, especially for the higher viscosities.

The temperature changes in the oil could be controlled by adjusting the volume of oil in circulation. If the temperature rise was too fast the entire volume of oil could be utilized by circulating through upper and lower storage tanks. A differential temperature between upper and lower tank also permitted to arrest the rise in temperature during any run after some practice. Small increases in temperature were permitted, say 2 to 3 deg F, and their influence was determined by taking additional points immediately after each run over the same range. Corrections to a constant temperature and hence to a constant viscosity could be made therefore in the analysis. However, usually such corrections were too small to influence the maximum efficiency in location and magnitude.

Analysis of Test Results

(a) *Computation Procedures.* As pointed out before, all data necessary for the performance calculations are contained on a 35-mm film strip which could be projected, point by point, on a screen made of tracing cloth. The readings were taken down by an observer behind the screen. The gages showed throughout the experiments very steady readings; fluctuations were largely eliminated by the viscous action of the oil in the connecting lines and by symmetrical constrictions in the mercury-manometer blocks. Two exposures were taken for every point, in order to discover changes in readings and to insure that all the information could be read clearly. If poor test points were discovered later in plotting the results, they were invariably traced to faulty readings from the film and were easily corrected by checking. The value of preserving thus on film the original measurements cannot be overemphasized, especially when insufficiently trained personnel must be entrusted with a major portion of the computing work.

The entire calculation procedure involving a great many steps was carefully worked out, so that a standard routine could be followed throughout and the evaluation of data from the film to the final performance graph could largely be left to personnel without technical training. Viscosities and specific gravities, velocity-head corrections, and discharge coefficients were read from graphs plotted to simple linear scales.

Since the discharge manometer in many runs indicated very small differences due to the exclusive use of the 8 × 4.92-in. orifice meter, these readings were also read directly, which upon comparison with the readings obtained from the film showed very good agreement. It was found practical then to take down also the speed and the torque readings during the run so that some calculations could be started immediately after the runs were taken, before the films were developed.

Pressure readings were not corrected for pipe friction losses between pump flange and piezometer connections. This refinement would have introduced additional computing work to an extent unjustified by its merits, the pressure connections in each case being located only one pipe diameter from the flanges. It is natural also that the percentage error in the over-all efficiency becomes greater for higher viscosities, so that the foregoing correction stays usually within the permissible margin. It may be stated that the accuracy of the results is referred to the efficiency loss

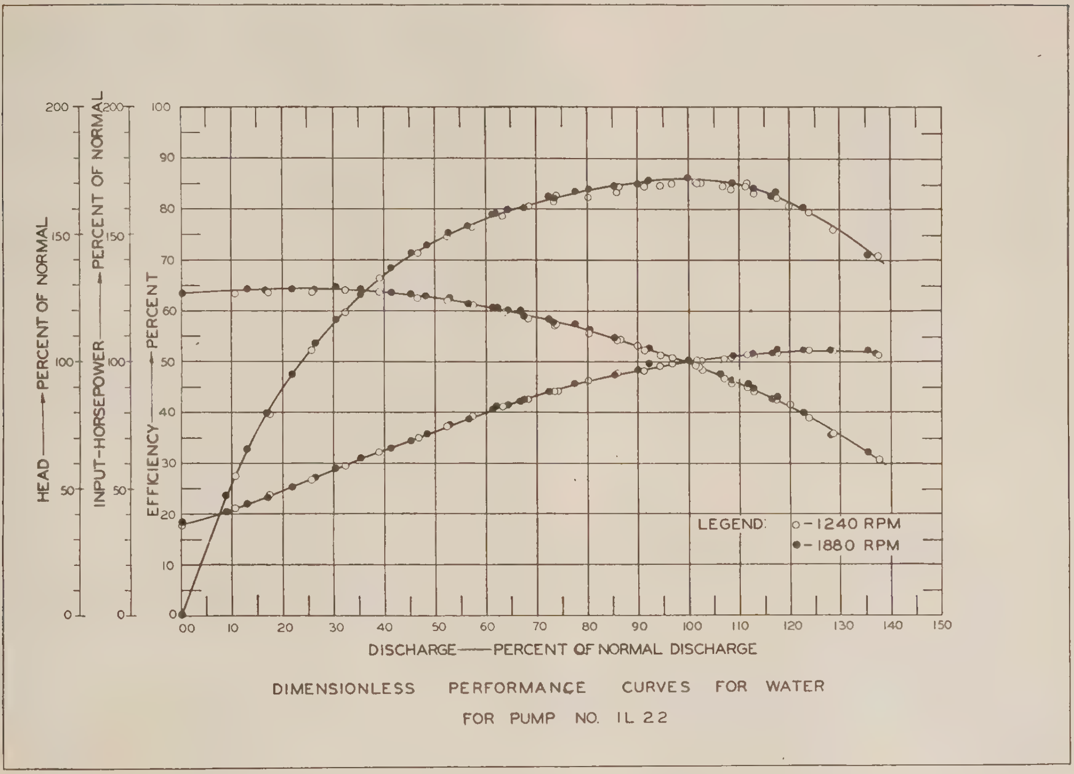

FIG. 8 EXAMPLE OF DIMENSIONLESS PERFORMANCE CHARACTERISTICS FOR WATER

$(100 - e)$ rather than to the efficiency (e) itself and that it is kept to ± 1 per cent in the average for $(100 - e)$.

(*b*) *Performance Characteristics.* Complete performance characteristics were plotted for all runs taken and discrepancies were therefore easily discovered. The influence of accidental errors is thereby minimized. Curves for successive runs were compared according to the order of their viscosities. These performance curves available for every run should yield upon further analysis additional experimental information concerning relative distribution of disk and ring losses, and on the operation near shutoff as well as at capacities larger and smaller than normal. The results presented in the following pages therefore touch only upon one phase of the problem under discussion, since maximum efficiency and normal capacities, head, and inputs are the only quantities considered at present in order to limit the scope of this paper.

ANALYTICAL PART

THEORY OF VISCOUS LOSSES IN CENTRIFUGAL PUMPS

(*a*) *Hydraulic Losses.* The so-called "hydraulic losses" in centrifugal pumps have been rather loosely defined in the past, since the thinking was predominantly influenced by the performance of pumps with thin fluids. With more viscous fluids the term "hydraulic losses" is here more definitely applied to the so-called "through-flow" losses, which are directly the result of skin friction and eddy systems along the primary path of the fluid passing through the pump. It is of course not possible to analyze these losses separately, since they depend on a considerable number of geometric variables, which may be briefly stated as follows:

1 Suction-pipe dimensions and shape of inlet which determine the state of flow at the entrance.

2 Design of pump inlet, eye diameter or its equivalent.

3 Shape, length, curvatures of impeller passages, contraction or expansion of cross sections.

4 Dimensions of volute, design of spiral, and diffuser.

It follows that in general the flow is nonuniform and that therefore pipe friction factors are not very useful here except in a very general way. In addition the curvatures encountered make any approach on the basis of boundary-layer theory impossible. A few general statements may be in order, however, in view of the conditions stated.

1 Every pump follows its own law of hydraulic resistance. Only the total losses can be determined experimentally, since they are interdependent.

2 Theories of individual losses will at best give only a very approximate quantitative explanation of the pump behavior. This may be extremely valuable, however, for the designer.

3 The relative weight of the losses will shift as a function of the specific speed and of Reynolds number. While skin-friction losses similar to pipe flow may predominate at low specific speeds, "body-resistance" losses will come to the fore with a change from radial to mixed and more or less axial flow for higher specific speed. In other words, since losses depend to a considerable extent on approach conditions, the character of the flow through the pump is more and more determined by the state of flow in the approach to the pump when higher specific speeds are reached. The relative length of the pump passages decreases with increasing specific speeds.

On the basis of these remarks, experimental results are indeed

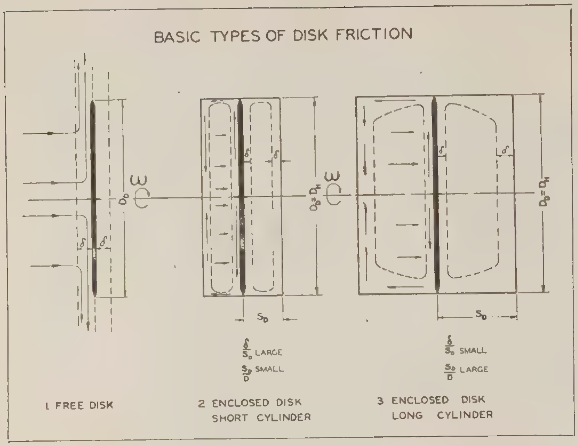

FIG. 9 BASIC TYPES OF DISK FRICTION

approached with hesitation. In retrospect it seems remarkable that the multitude of possible losses and geometric dissimilarities nevertheless produces statistical averages with a relatively narrow zone of deviations, as long as ring and disk friction losses remain comparable for the various pumps.

Energy losses for flows of a complex nature are customarily expressed in terms of velocity head of the mean flow. Choosing relative velocity at impeller exit as a suitable one, the difference between the head produced for water and the head for oil can be written as

$$H_l = (H_w - H_0) = C_R \cdot \frac{v_2^2}{2g} = C_R \cdot \frac{Q'^2_0}{a_2^2 \cdot 2g}$$

or dividing both sides by H_0

$$\frac{H_l}{H_0} = \left(\frac{H_w}{H_0} - 1\right) = C_R \cdot \left(\frac{Q'^2_0}{H_0}\right) \cdot \frac{1}{2g \cdot a_2^2} \quad \ldots\ldots\ldots [1]$$

wherein C_R is a function of Reynolds number, pump-design, and of roughness. Since $Q_0'^2/H_0$ was found practically constant for a wide range of Reynolds numbers, C_R can be obtained, if the water performance is known, from the plot of H_0/H_w against Reynolds number.

The question of a suitable Reynolds number was naturally the subject of considerable analytic experimentation. Eventually no particular advantage was found in any one as compared to another. However, the four fundamental forms stated below were calculated for all test points.

$$R_D = \frac{\omega \cdot r_2^2}{\nu} = \frac{u_2 \cdot d_2}{2 \cdot \nu} = \frac{\phi \sqrt{2gH_0} \cdot d_2}{2 \cdot \nu} = 2620 \frac{Nd_2^2}{\nu \cdot 10^5} \quad \ldots [2a]$$

$$R_H = \frac{\sqrt{H_0} \cdot d_2}{\nu} \quad \ldots\ldots\ldots [2b]$$

$$R_S = \frac{v_i \cdot d_{i_e}}{\nu} = \frac{283.7 \cdot Q_0}{d_{i_e} \cdot \nu \cdot 10^5} \quad \ldots\ldots\ldots [2c]$$

$$R_P = R_S \cdot \frac{d_{i_e}}{d_2} = \frac{283.7 \cdot Q_0}{d_2 \cdot \nu \cdot 10^5} = \frac{283.7 \cdot Q_0 \cdot b_2}{b_2 \cdot d_2 \cdot \nu \cdot 10^5} \quad \ldots\ldots\ldots [2d]$$

R_D and R_H differ essentially by the factor $\phi = u_2/\sqrt{2gH_0}$. Since ϕ very seldom differs greatly from unity, the reason for the small differences found in plotting the results against both is readily apparent. A small change in Reynolds number has little effect on the efficiency loss, while the differences due to pump design are more pronounced. The relatively best agreement between results for various pumps, especially for low Reynolds numbers, was obtained by using R_S, in which the equivalent or actual eye diameter of the impeller d_{i_e} was introduced as the characteristic length. For practical reasons R_D was chosen, since it is most readily calculated from known quantities. In addition disk and ring friction losses are most easily expressed as a function of R_D. It offers, therefore, the most systematic approach toward separation of the afore-mentioned losses from the so-called "through-flow" losses.

(*b*) *Disk Friction.* The problem of friction losses due to the rotation of a circular disk in a fluid has received the attention of investigators in theory and by experiments. A comprehensive view of this problem, however, has been lacking and thus the fact remained obscured that the theoretical and experimental findings of the various investigators show considerable agreement, if the various phases of the problem are systematically related. Fig. 9 illustrates the basis on which the subsequent treatment rests. Two papers (6, 7) attack the following problems.

1 The disk rotating in an infinite space, filled with fluid.

2 The disk rotating in a housing of approximately equal diameter and with small clearances between disk and housing.

Case 1. Von Kármán (6) dealt with problem 1 and established that the resistance mechanism depends entirely on the formation of a boundary layer adjacent to the surfaces of the disk, within which the tangential velocity of the fluid increases from zero to $\omega \cdot r$. The theoretical velocity distribution within this boundary-layer is given by Fig. 10 for the laminar case. This layer functions like the impeller of a pump. Since the pressure on the periphery of the disk is atmospheric, a radial flow q_D results into the surrounding fluid at rest with an angular momentum $u_2 \cdot r_2$ per unit of mass. On this basis von Kármán established the basic equations summarized below for laminar and turbulent flow. It is to be noted at this point that all kinetic energy imparted to the fluid by disk action is dissipated in the surrounding space. In general the torque to be applied is defined for one side of the disk by

$$T_D = C_D \cdot \gamma \cdot r^3 \cdot \frac{u_2^2}{2g} \quad \ldots\ldots\ldots [3]$$

(*a*) In the case of laminar flow, which is of particular interest here, the boundary-layer thickness is given by

$$\frac{\delta}{r} = \frac{2.58}{\sqrt{R_D}} \quad \ldots\ldots\ldots [4]$$

and the discharge of the disk by

$$q_D = 0.137 \cdot (2\pi \cdot r \cdot \delta) \cdot u$$

The so-called coefficient of friction becomes

$$C_D = \frac{1.84}{\sqrt{R_D}} \quad \ldots\ldots\ldots [5]$$

(*b*) For turbulent flow and a "smooth" disk, one for which all roughness irregularities remain submerged in the laminar sub-layer, the boundary-layer thickness is

$$\frac{\delta}{r} = \frac{0.462}{R_D^{1/5}} \quad \ldots\ldots\ldots [6]$$

on the basis of the seventh-root law for the velocity distribution.

The so-called friction coefficient becomes

$$C_D = \frac{0.0728}{R_D^{1/5}} \quad \ldots\ldots\ldots [7]$$

Equations [5] and [7] are plotted as lines A and B in Fig. 11. The application to "rough" disks has not been carried through, but it is obvious that the treatment is analogous to the friction problem for flat plates and will give an expression involving the ratio ϵ/δ, wherein ϵ stands for absolute roughness. The scattering of experimental results obtained by different experimenters for large Reynolds numbers R_D is probably due to variations in ϵ/δ. This case, however, is of little importance for the problem here.

Case 2. The second case defined before was treated experimentally and theoretically by Schultz-Grunow (7) and was essentially confirmed by the excellent experiments of Zumbusch as quoted in the same paper, the results of which are represented by line E in Fig. 11. The basic assumptions for this case should be clearly kept in mind for the later discussion of the differences in von Kármán's and Schultz-Grunow's results. The cylindrical wall surrounding the disk is assumed nearly equal in diameter to the disk and is short enough axially so that friction losses on the periphery may be disregarded. Thus the fluid is confined to the space between disk and housing and the angular momentum imparted by the disk is no longer lost to the surrounding fluid. Since the circular housing plates must exert a torque equal and opposite to the torque applied to the disk, it follows that the fluid confined to the space between them must revolve with one half of the angular velocity of the disk, so that equal frictional shears may be developed on disk and circular housing plate. This fact also is confirmed by experiments and is a common assumption.

Schultz-Grunow obtained for the one-sided disk for

(*a*) Laminar flow

$$\frac{\delta}{r} = 2.17 \frac{1}{\sqrt{R_D}} \qquad [8]$$

$$C_D = \frac{1.334}{\sqrt{R_D}} \qquad [9]$$

(*b*) Turbulent flow

$$C_D = \frac{0.0311}{R_D^{1/5}} \qquad [10]$$

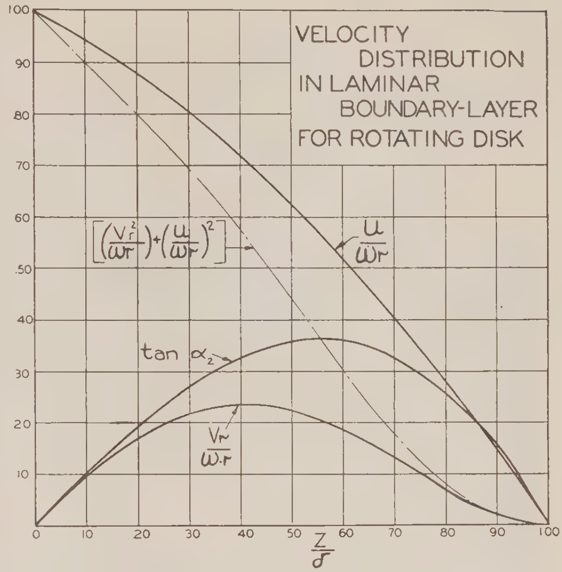

Fig. 10 Velocity Distribution in Laminar Boundary Layer Near Rotating Disk

These results are given as lines C and D_1 in Fig. 11.

Case 3. A more general approach to the disk-friction problem becomes now possible as a result of the work discussed as Cases 1 and 2. Using von Kármán's expressions, a general equation can be written for the frictional torque for a differential angular velocity ($\omega_D - \omega$). ω now denotes the angular velocity of the confined fluid, while ω_D represents the angular velocity of the disk. The results of this analysis may be reserved for a future paper, since space is lacking at this time. However, it is interesting to see the results of this analysis for the special case of $\omega/\omega_D = 1/2$. Introducing the latter ratio, the corresponding values of C_D are for

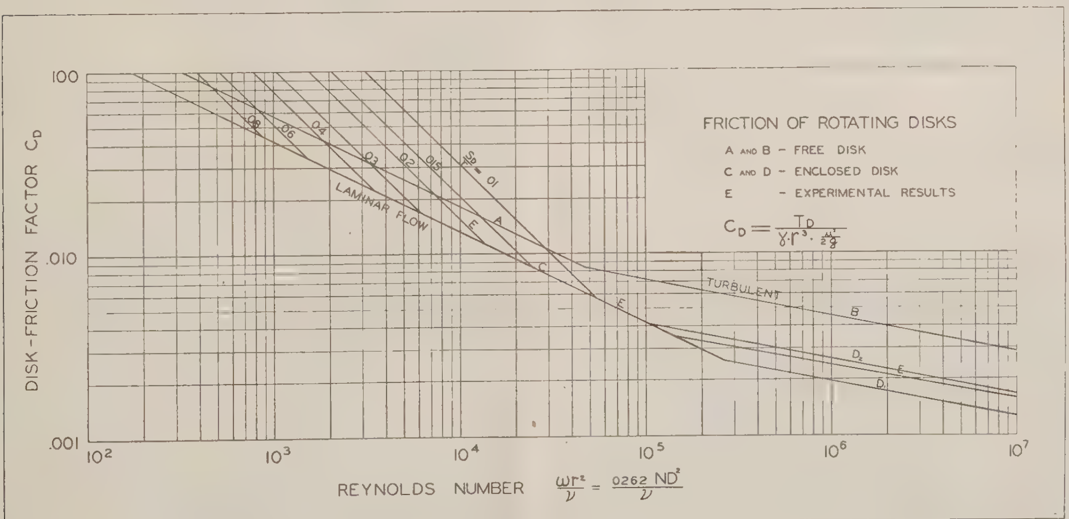

Fig. 11 General Reynolds Number Plot of Disk-Friction Coefficients

(*a*) Laminar flow

$$C_D = \frac{1.300}{\sqrt{R_D}} \quad\text{[11]}$$

(*b*) Turbulent flow

$$C_D = \frac{0.0418}{R_D^{1/6}} \quad\text{[12]}$$

with corresponding lines C and D_2 in Fig. 11. It is seen that von Kármán's equations applied properly check Schultz-Grunow's results extremely well for laminar flow. For turbulent flow the agreement is not as good, but Equation [12] checks the experimental evidence better than Equation [10], since values for the numerical constant obtained experimentally increase from 0.037 to 0.040 with higher Reynolds numbers. The experimental result permits another interesting conclusion, namely, the influence of friction on the cylindrical housing is increasing relative to the circular wall friction, since the boundary-layer thickness δ decreases with increasing Reynolds numbers, while the clearance between disk and housing, S_D, is constant. In other words, ω decreases in terms of ω_D.

The general conclusions for the influence of disk friction on pump performance especially for viscous fluids are therefore as follows. Theoretically the case discussed by von Kármán (see Case 1) represents the maximum disk friction which requires $\omega = 0$ or $\omega = \omega_D$. Neither condition exists normally in pumps. The conditions generally met in pumps are discussed as Case 3, with $\omega \gtrless {}^1/_2\,\omega_D$. The special case $\dfrac{\omega}{\omega_D} = {}^1/_2$ gives a theoretical minimum disk friction. A further more extensive discussion must be delayed at present.

Case 4. Special Case of Small Clearances S_D. A clearance is said to be small here, if radial velocities become zero and if the tangential-velocity gradient becomes constant across the axial clearance S_D. An elementary analysis gives

$$C_D = \frac{\pi}{R_D}\cdot\frac{r}{S_D} \quad\text{[13]}$$

Comparing this expression with Equations [11] and [4] as modified for the case of $\dfrac{\omega}{\omega_D} = {}^1/_2$ so that

$$\frac{\delta}{r} = \frac{3.65}{\sqrt{R_D}} \quad\text{[14]}$$

the following relation between S_D and δ is derived

$$\frac{\delta}{r} = 1.51\,\frac{S_D}{2r} \quad\text{[15]}$$

This equation represents the intersections of the C_D vs. R_D lines in Fig. 11, where the laws of resistance change from Equation [11] to Equation [13]. The influence of the boundary layer disappears therefore as soon as the total boundary-layer thickness (2δ) is of the order of magnitude of the clearance S_D. The transition is naturally a gradual one. The factor 1.50 instead of unity is explained by the velocity distribution in the boundary layer and by the fact that the law for small clearances takes full effect only after the gradient of the velocity has become uniform throughout the width S_D. Necessary minimum clearances for pumps lifting viscous liquids can be calculated from [14] and [15] to avoid excessive disk friction. Of course the length δ need not enter at all, once its physical significance is recognized and one may write directly the expression for the minimum clearance S_D in terms of a limiting Reynolds number R_{Dl}

$$R_{Dl} = 5.83\left(\frac{d_2}{S_D}\right)^2 \quad\text{[16]}$$

below which the disk friction would be unnecessarily large. While [15] and [16] have been obtained on the basis of $\omega/\omega_D = {}^1/_2$, they do not necessarily depend seriously on this exact value, since the total thickness of the boundary layers remains fairly constant for $\omega/\omega_D = {}^1/_2$. A decrease of δ near the rotating disk will be compensated by an increase of δ' near the circular housing plate and *vice versa*.

(*c*) *Ring Losses.* Considering losses due to the wearing rings it is clear that the discussion must be concerned with two different types of losses:

1 Leakage of fluid through the annular space due to the pressure difference between entrance and exit section.

2 Torque losses due to the tangential shear developed by the rotation of the pump ring within the stationary housing ring.

The attention of the pump designer has been focused mainly on the leakage losses, since thin liquids will readily pass in quantity even through small clearances and since the torque losses for such liquids remain small. It is clear that the general thinking must be revised as soon as the pumps are used to lift viscous fluids, which are 10 to 2000 times more viscous than water.

After a careful scrutiny of all information on hand (9, 10, 11, 12), considerable analytical work, which cannot be included here, established the following points:

(*a*) Leakage is not affected by rotation, as long as turbulent flow in the clearance space persists.

(*b*) Leakage will be affected by rotation whenever rotation changes the state of flow from laminar to turbulent in the ring-space.

(*c*) In pumping oils the leakage flow is usually laminar and is reduced very fast to an insignificant quantity. Temperature gradients along its path, however, prevent ready calculation of its magnitude. Volumetric efficiency is approaching unity.

(*d*) The torque losses due to the tangential shear developed are increasing considerably in magnitude and greatly affect the over-all efficiency.

(*e*) Reduction in leakage and increasing torque losses influence the running temperature of the pump and therefore the over-all efficiency.

Points (*c*) to (*e*) deserve further discussion. It is clear that reduction in leakage concentrates the dissipation of increasing torque losses within a smaller and smaller volume of liquid. Considerable heating must therefore be expected, which is fortunate indeed, since otherwise the viscous torque would very soon become excessive. As it is, the oil entering the ring space is absorbing the torque losses and is heated up with consequent reduction in viscosity, which in turn reduces the viscous shear and increases somewhat the leakage. A considerable temperature-gradient exists along the axial length of the ring. Naturally the problem is a rather difficult one, since the increase in temperature depends on the flow of heat from the ring surfaces, the exchange of heat from the rings to the oil leaking through, and on the temperature-viscosity function of the oil itself. However, some analytical solution is possible on the basis of adiabatic flow, which furnishes at least a rather useful qualitative explanation of the phenomena encountered in the analysis of the pump test results. The results of this solution show that differences in efficiency must be ob-

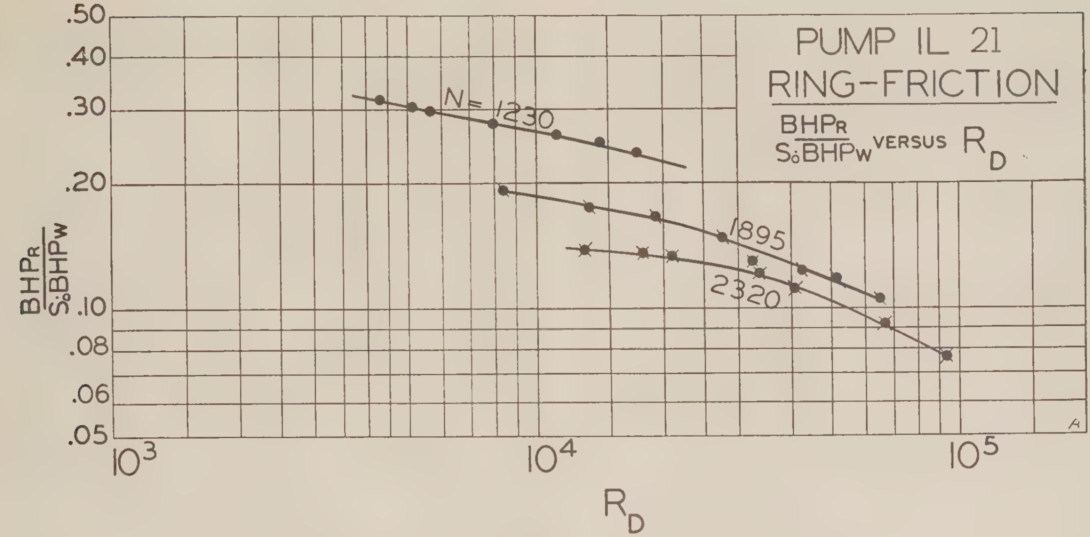

FIG. 12 EXAMPLE OF RING FRICTION AS A FUNCTION OF SPEED AND OF R_D

tained for the same Reynolds number R_D, if the speed of rotation is changed.

The horsepower loss BHP_R due to the tangential shear for one ring is given by the equation

$$BHP_R = \frac{3200 \cdot S_0}{\xi \cdot R_D} \cdot \frac{b_R}{S_R} \cdot \left(\frac{d_R}{d_2}\right)^3 \cdot \left(\frac{N}{1000}\right)^3 \cdot d_2^5 \ldots\ldots [17]$$

This equation is easily derived by assuming a constant viscosity except for the dimensionless factor ξ. The latter is a function of the temperature gradient along the ring length b_R, of the temperature-viscosity relation for the oil and of the ring dimensions. This factor ξ is therefore responsible for the breakdown of hydraulic similarity, in so far as the ring flow is concerned, since obviously a constant ξ would result in a continuous curve for BHP_R as a function of R_D. Using the analytical and numerical results obtained for ξ, the ratios $BHP_R/S_0 \cdot BHP_w$ have been plotted for three speeds against R_D for pump IL 21. The latter shows the effect of ring friction most clearly. It may be stated again that these analytical results should be judged as qualitative rather than quantitative, until more evidence becomes available. The plot, however, brings out clearly that the shift in power and efficiency-loss curves found in Figs. 14 to 16 for the various speeds is at least partly due to ring losses.

It can further be shown that increasing the ring clearance or shortening of the axial length of the rings does not have a corresponding effect on the power losses. This has also been proved by a few experiments, which, however, are not sufficiently complete to allow general conclusions at this time. The reasons for this behavior are probably that both measures produce increased leakage, thereby increased cooling and correspondingly higher tangential shear.

(*d*) *Miscellaneous Losses.* The only losses not discussed so far are stuffing-box losses and bearing losses. The latter are not affected by the type of liquid pumped and little need be said about them here. The stuffing-box losses are of the same type as the ring losses; their variation with the Reynolds number for any given pump will accentuate the tendency toward dissimilarity of hydraulic behavior, produced by the influence of the ring losses.

SUMMARY OF EXPERIMENTAL RESULTS

(*a*) *General Discussion and Methods of Presentation.* All experimental data were plotted in the customary way, i.e., performance curves showing input horsepower, head, and efficiency were plotted against discharge from complete shutoff to the maximum flow, which was always larger than the normal flow. All analysis work started from these basic curves, of which there are more than 220 covering a range of viscosities from that for water to 10,000 SSU. The analysis as carried out in the following is only concerned with the effect of viscosity on the so-called "normal performance points" of the pump, i.e., on the maximum efficiency. The influence of the viscosity on the shape of the performance curves may give considerable insight into the relative distribution of the various losses. Time at present did not permit, however, any further exploitation of these results, which must be reserved for a future date. In the following are given the methods which were followed to obtain systematically the variation of maximum efficiency, head, and input-horsepower with increasing viscosities:

1 The first approach considered the normal discharge for water as a constant also for the oil runs. Corresponding efficiencies and heads were obtained from the oil-performance curves and dimensionless correction curves were plotted as a function of Reynolds number. This was feasible only for lower viscosities and seemed to provide a good basis for comparison with water runs since all average velocities remain the same for water and oil runs. Thus the influence of viscosity is shown immediately and clearly. Increasing viscosity causes changes in the velocity distributions everywhere in the pump, which tend to become more and more nonuniform. Thus the kinetic-energy content of the flow must increase at the expense of the potential energy and, in addition, friction losses also grow rapidly for lower Reynolds numbers. The conversion of the kinetic energy to potential energy is naturally accompanied by higher losses. The size of the volute may not favor the same efficiency of conversion as for water. Furthermore, the velocity-head corrections are calculated on the basis of average velocities rather than on the basis of true kinetic-energy contents. A large decrease in head is therefore noted together with the lowering of the efficiency. Since

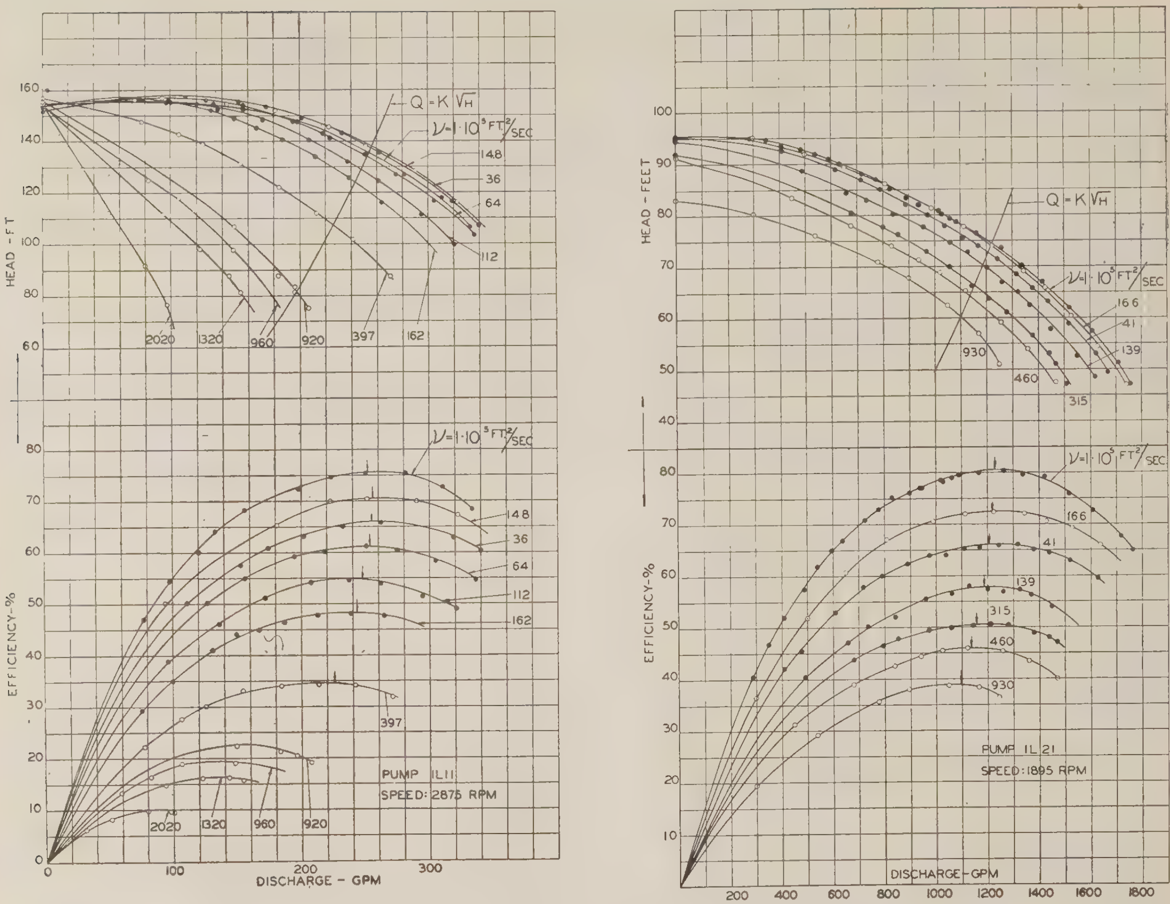

Fig. 13 Examples of Head-Capacity and Efficiency-Capacity Curves for Various Pumps and Viscosities

the efficiency on the basis of constant Q_0 departs markedly from the maximum or peak efficiency for higher viscosities, the method proved very soon impractical, as can be seen from Fig. 13, and was therefore given up.

2 At times it has been suggested to assume a constant head, regardless of viscosity. This gives normal capacities which are very soon much lower than the one corresponding to maximum efficiency as can easily be verified on Fig. 13. However, for viscosities up to 100 SSU either method may be used without introducing large errors.

3 It was found that if the ratio $(Q_0/\sqrt{H_0})$ was assumed to remain constant as calculated from the water performance, a parabola could be plotted, which would intersect the head-discharge curves at the point of maximum efficiency, as shown in Fig. 13. This proved to be especially helpful in view of the fact that for lower viscosities it is impossible to decide by inspection only on a point of maximum efficiency and corresponding normal discharge, head, and power. This method was used therefore in plotting the information presented in the following graphs, which represent the essential results of the study for easy reference. These graphs give the complete Reynolds number characteristics for the practical range of operation for all four pump variants.

(b) *Influence of Viscosity on Performance.*

1 Normal Head and Capacity. A few general remarks are in order to explain Figs. 14 and 15. All heads and horsepower inputs are given in terms of their corresponding water equivalents and are plotted against R_D. The efficiency loss $(100 - e)/100$ was plotted in preference to the efficiency, since logarithmic scales are used, so that accidental errors are shown in correct proportion. All curves show the water performance points on the right-hand side in black with special marks to identify the different speeds. The points for thin oil are white, followed by light oil points in black, and finally the points for heavy oil are white again. This identification by liquids proved desirable, since differences in performance were discovered as the liquid was changed, even though the Reynolds numbers remained of the same order of magnitude. The explanation for these differences is given later with the reasoning relative to the shift of curves with speed. The general trend of the curves is self-explanatory with decreasing heads and with increasing power input and efficiency losses as the Reynolds number decreases. The striking influence of the disk-friction losses becomes apparent by comparing Fig. 11 with Figs. 14 and 15. The steep rise in efficiency losses is directly traceable to the change from turbulent to laminar disk-friction losses. A special curve for reduction in capacity was found unnecessary

since the discharge Q_0 can be obtained from H_0 on the basis of $Q_0 = K\sqrt{H_0}$ wherein $K = Q_w/\sqrt{H_w}$. The latter relationship was found to hold true for Reynolds numbers R_D as low as 3000 to 4000. Below these values of R_D the capacity decreased more rapidly, the head-capacity curves became very steep and the points of maximum efficiency had to be picked by inspection. This, of course, results in greater scattering of the points, since at the same time the general accuracy becomes lower. A slight shift in the capacity may produce an extremely large change in the head. However, it is felt that the lower limit of $R_D = 4000$ will terminate almost any range that might come up in actual practice.

2 Input Power. The input power curves represent a correction factor by which the water horsepower input (BHP_w), as corrected for specific gravity, is to be multiplied to get the horsepower input for oil (BHP_0). These curves indicate a rather large increase in the latter for Reynolds numbers, for which the head and capacity corrections are almost insignificant. This would be further proof of the contention that the decrease in efficiency and the increase in power input for Reynolds numbers near the 100,000 mark is mainly due to the disk and ring friction. It should also be noted that pumps IL 11 and IL 22 show the largest increase here, while IL 21 with a small impeller but relatively large rings and IL 12 with an open impeller show smaller values. The rise in input horsepower for lower values of R_D is more or less linear in a log-log plot, corresponding to the change with Reynolds number of all hydraulic losses including disk and ring friction. For all pumps, differences in power input are found for constant Reynolds numbers as a function of speed. This may be explained in part by the effect of ring and stuffing-box friction as outlined in a previous section. The running temperature for higher speeds increases, this in turn causes a reduction of the shearing stresses, and thereby a reduction also in the percentage of ring losses in terms of total power input. The larger the power output for a given pump, the smaller will be the ring losses in per cent of input power for the same Reynolds number.

It is obvious then that these differences should be most conspicuous for pump IL 21 where the output was very small and that the difference between low and medium speed for pump IL 22 is much less, since the impeller of the latter was 35 per cent larger in diameter for the same inlet and ring dimensions. It is clear, furthermore, that the results for pump IL 11 will show the influence under discussion even less, since the rings here are very small in proportion to the impeller and therefore have but little effect on the total losses. The stuffing-box losses will accentuate the phenomenon, since IL 21 and IL 22 are double-suction pumps, while IL 11 is of the single-suction type. The disk-friction losses in contrast to the ring-friction losses will in general be larger for low-specific-speed pumps. They will therefore affect the performance of IL 11 most of all and will have a minimum effect on the behavior of IL 21. This, of course, was one of the reasons for selecting these pumps. It should also be mentioned that the curves for power input correction and efficiency loss for the low speed are probably not of practical value, since such speeds are seldom employed. They were included in these tests mainly to bring out the effect of speed and in order to increase the range of Reynolds number for each oil.

3 Maximum Over-All Efficiency. The tendencies of the head and input-power correction curves are essentially reflected in the plot of the ratios $(100 - e)/100$ against Reynolds number. These curves will show all the discontinuities encountered with each of the other types to a somewhat larger scale. The question may be asked, why the efficiency loss was not given as a fraction of the efficiency loss for water. The argument against the latter method would be that the efficiency loss itself represents already, to a certain extent, a dimensionless factor of resistance for a given type of pump, similar to the pipe friction factor (f) for a given pipe with relative roughness (ϵ/d)[5]. Just as it would be unwise to divide all pipe-friction factors by the special values of (f) obtained for various values of ϵ/d, so nothing could be gained by dividing all efficiency losses by the water efficiency. Since all efficiency losses remain constant with respect to Reynolds number in the range of water or air performance, while Reynolds number determines the behavior for more viscous liquids, the analogy to pipe-friction phenomena is close. The relative roughness of the pipe would find its counterpart in a specific speed modified to include a relative-roughness parameter. However, such an undertaking must be postponed until such time when more experimental material, systematically sifted and co-ordinated, is available. The efficiency-loss curves for low Reynolds numbers show a reversal of the trend at which the losses increase. It was pointed out before that below Reynolds numbers of $R_D = 3000$ to 4000 the capacity decreases at a much faster rate than above those values. A special capacity correction curve should have been added, which, however, was not believed necessary in view of its negligible practical significance and of the somewhat uncertain evidence which permits a wide interpretation, as can easily be seen in Fig. 13. If wanted, it can of course be calculated from the other curves.

There is, however, an interesting explanation for the lower rate of increase of the efficiency losses, which takes into account the heat exchange in the pumps. If no heat were developed by ring, stuffing-box, and disk friction, the efficiency would reach insignificant values very fast. As it is, the heat developed when heavy oils are pumped, will slow down this development considerably. As the capacity decreases the cooling of the pump body decreases, so that the efficiency-loss curve will approach a value of unity only for very small Reynolds numbers. The ultimate performance will be such that oil can be pumped only as it is warmed up by the dissipation of almost the entire power input into heat. The fact that this tendency became apparent in the curves also points to the limits of the practical use to which centrifugal pumps may be gainfully employed in pumping viscous liquids.

Because it was desired to show the application of a different Reynolds number, the results for pumps IL 11 and IL 22 have been plotted against $R_S = (283.7 \cdot Q_0/d_{ie} \cdot \nu \cdot 10^5)$. This, as is shown in Fig. 16, results in changing the order of magnitude of the Reynolds number by a factor of ten and since Q_0 will decrease somewhat with Reynolds number, the curves will be stretched over a wider range. But essentially nothing new is gained from this plot and the difficulty of having an unknown quantity Q_0 in the expression for R_S makes its usefulness quite doubtful.

GENERAL CONCLUSIONS

General Reynolds Number Characteristics

The results of the experimental and analytical work described so far show clearly that resistance of a centrifugal pump can be represented by distinct curves plotted against Reynolds number $R_D = 2620(Nd_2^2/\nu \cdot 10^5)$. Three curves are normally required to describe the behavior as a function of Reynolds number R_D:

1 Ratio of normal head for oil H_0 to the normal head for water: H_0/H_w

2 Ratio of normal power input for oil BHP_0 to the normal power input for water corrected for specific gravity: $BHP_0/(s_0 \cdot BHP_w)$.

3 The efficiency e or better the efficiency loss $(100 - e)$.

The capacity correction for the practical range of operation Q_0/Q_w is equal to the square root of the head correction: $\sqrt{H_0/H_w}$.

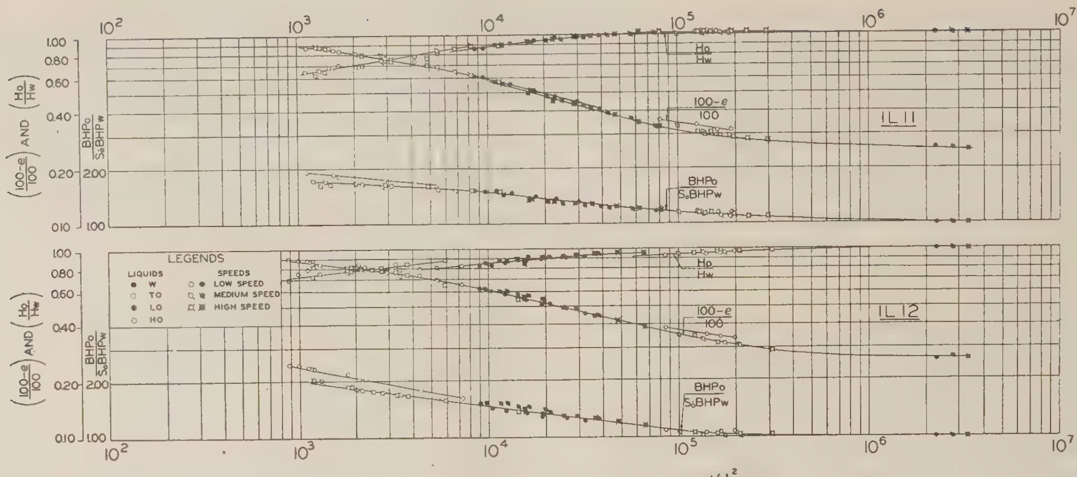

Fig. 14 Results Plotted Against R_D for Pump IL 1

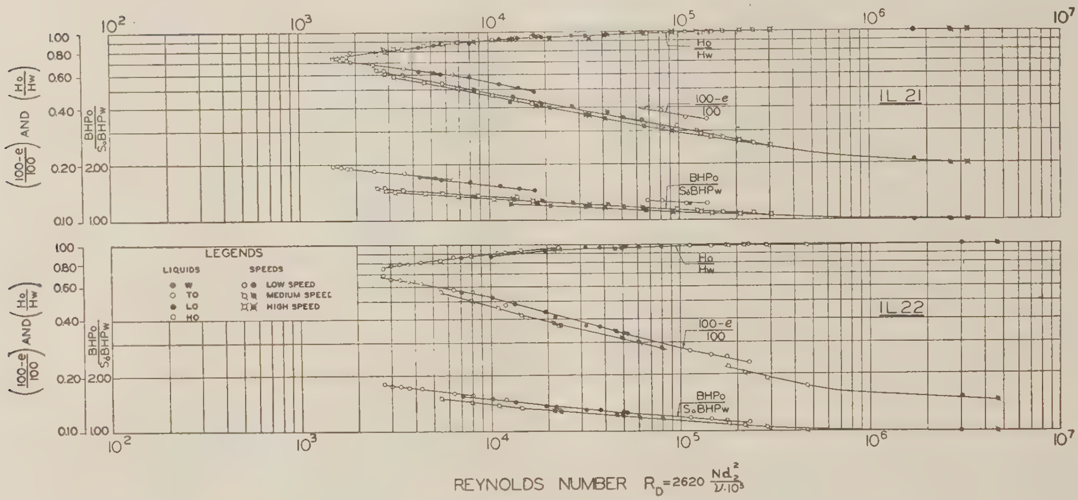

Fig. 15 Results Plotted Against R_D for Pump IL 2

In order to facilitate the conversion from the conventional SSU units for the viscosity to $\nu \cdot 10^5$ in square feet per second as used for the computing of Reynolds number, the equations of conversion may be stated here

$$\text{for SSU} > 100, \quad \nu \cdot 10^5 = \left(0.237\ \text{SSU} - \frac{140}{\text{SSU}}\right) \ldots\ldots [18]$$

$$\text{for SSU} < 100, \quad \nu \cdot 10^5 = \left(0.244\ \text{SSU} - \frac{210}{\text{SSU}}\right) \ldots\ldots [19]$$

In Fig. 17 the Reynolds number characteristics for the "normal" pumps IL 11 and IL 22 have been summarized for the purpose of practical application. It is proposed to use these curves for making general corrections for a range of specific speeds from 800 to 2200 approximately. Values for pumps of different water efficiency may be interpolated.

It is of importance that the experimental material basic to the eventual adoption of correction curves be greatly increased by further analysis and co-ordination of available information and possibly by additional testing. It is naturally desirable to translate eventually all the calculations necessary at present in using these curves into graphical and tabular form for easy application in practice. It was felt, however, that it would be valuable to have first the benefit of an extensive discussion by all those interested in this problem, before too much time is spent in adapting the present results to practical use.

Influence of Design Features on the Reynolds Number Characteristics

The general trend of the Reynolds number characteristics indicates three different zones within which the influence of the major losses is changing in weight.

1 For the range of water and air performance above $R_D \approx 10^6$ the efficiency losses are essentially due to the hydraulic

"through-flow" losses, followed in importance by disk friction and by leakage.

2 For Reynolds numbers $R_D \approx 10^6$ down to $R_D \approx 10^4$ the increase in power input is caused mainly by rapidly growing disk and ring friction losses, while through-flow losses increase at a comparatively low rate. The latter fact is indicated by the relatively small decrease in head and capacity, which proves that turbulent flow persists essentially throughout the pump. Leakage losses have assumed a negligible part.

3 For Reynolds numbers lower than $R_D \approx 10^4$ the through-flow losses increase more rapidly as indicated by a marked downward trend in head and capacity. Laminar-flow conditions are gradually established for the main flow. Disk and ring losses become less dominant and due to the large dissipation of power into heat on account of the latter the general rise in the efficiency losses is retarded.

Due to the complex nature of the flow through a pump it is naturally impossible to fix any Reynolds number R_D for the beginning of laminar-flow conditions for any one pump. It is even less possible to determine such a critical Reynolds number as a general criterion for all pumps. However, it is quite obvious that such a value of R_D would have little critical significance and is in no way analogous in this respect to the critical Reynolds number for pipe flow. The complexity of the losses and the non-uniform character of the flow preclude a sharp break in the line of resistance and point toward a very gradual and smooth transition between the two states of flow. This is indeed the conclusion to be drawn from the curves of Figs. 14–17.

A few additional conclusions may be drawn with respect to design characteristics: The head correction curves show that for low viscosities and low specific speed (pump IL 11) the head may increase at first above that produced for water. This is

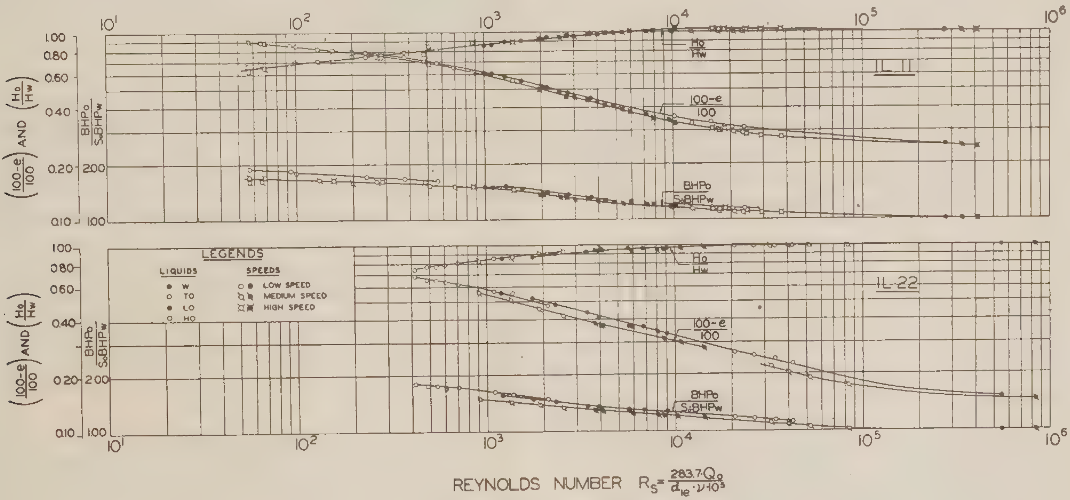

Fig. 16 Results Plotted Against R_S

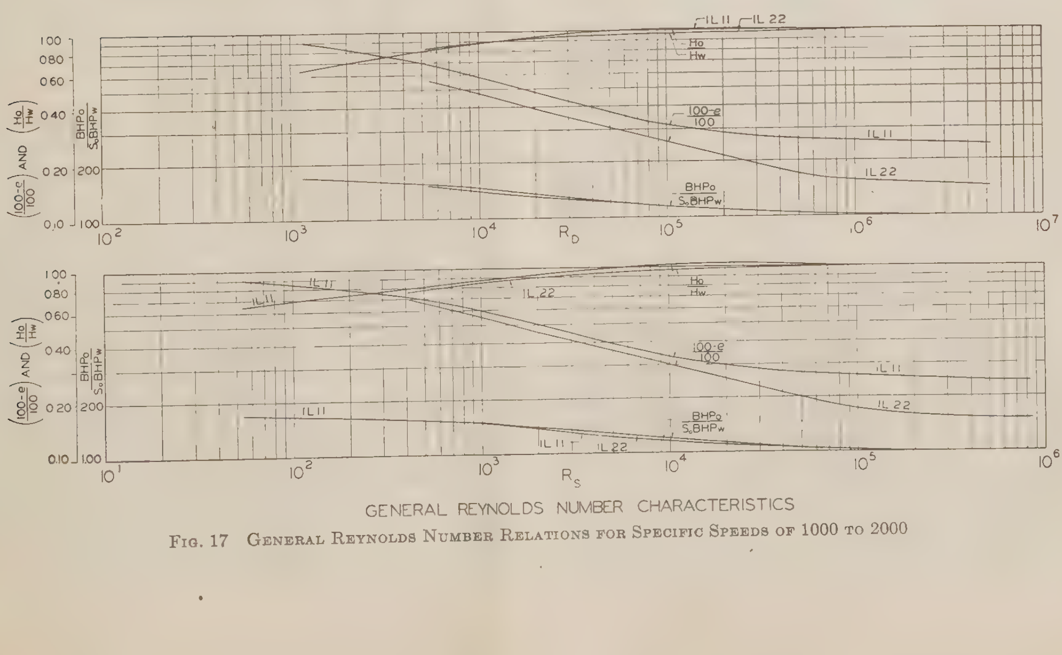

Fig. 17 General Reynolds Number Relations for Specific Speeds of 1000 to 2000

believed mainly due to the large effect of disk action for such pumps, since the pumping by disk action here becomes a considerable percentage of the total capacity. Further proof for this contention is supplied by the curves for the open impeller of the same pump, which show a lower head and lower power in the same range of Reynolds number.

If ring losses are to form a small part of the total losses, abnormally low speeds should be avoided. The useful output of a given pump is increased considerably for viscous conditions of flow by increasing the speed, since the influence of ring losses is diminished. This tendency is exemplified by the curves for the higher-specific-speed pump IL 21, which shows the greatest improvement with higher speeds, since ring and stuffing-box losses form a large percentage of the total losses for the lower speeds.

Individual losses, which are due to "hydraulic friction," to disk action, to ring and stuffing-box friction, are not easily separated at present but will vary apparently within reason in a proportional manner for pumps of conventional design. It may be assumed that a decrease in disk friction for a higher specific speed is compensated for in part by the relative increase in ring friction for this type of pump. However, there is still a net gain in efficiency when compared on the basis of constant Reynolds number and considering only the curves of Fig. 17. Compared on a percentage basis the efficiency losses differ less for low Reynolds numbers than for the water performance runs, since the curves converge rather rapidly for a certain range of R_D values.

A considerable increase in the running temperature for a given pump is caused by ring and stuffing-box friction. While the evidence on hand does not permit more than a qualitative estimate of the influence of the pump temperature on the performance, it may be stated that for a given Reynolds number and a given speed the efficiency is somewhat higher and the head produced is increased, if the running temperature is high. In the range of R_D, where Heavy Oil (HO) and Light Oil (LO) points overlap, the curves show a distinctly higher head for the former, since its temperature is high here while the Light Oil is cold. These remarks are made at this time with the intent of calling attention to the influence of the running temperature rather than with the idea of suggesting definite answers.

Attempts have been made during the evaluation of the data to analyze the individual losses separately and to deduct from the power input the influence of disk and ring friction. While expressions for disk friction give probably the order of magnitude of these losses correctly, the ring friction is not as easily calculated, since it is influenced to a decisive degree by large temperature changes in the ring space. For the time being, therefore, the attempt at isolation of the hydraulic losses from the input power was discontinued. But it is clear that eventually this phase of the problem will have to be solved, if further insight into the relative distribution of these losses is to be gained. This will be a very fruitful subject for further experimental studies.

Recommendations

On the basis of the information made available in this paper it is possible to propose some very definite future steps toward a final solution of the problem under discussion.

1 A considerable amount of detailed information, which up to date seemed irrelevant, should be disclosed by the profession as a result of the material published here. This material should be critically sifted and co-ordinated by a central agency on the basis of all the pertinent variables involved.

2 The information embodied in the performance curves and data, of which the results presented form an important but relatively small part, deserves further analysis. The influence of viscosity on part-load and overload operation should be cleared to a certain extent. Since disk and ring friction losses remain more or less fixed regardless of discharge, the detailed analysis of input and output curves should yield valuable information toward separation of these losses from the hydraulic losses.

3 The problem of ring friction should be studied further, analytically and experimentally. Applications toward improved stuffing-box design and use of mechanical seals may be included here.

4 Analytical studies should be undertaken to determine the influence of relative roughness and of specific speed as variables influencing the efficiency, so that eventually a set of universal performance curves may be plotted including these quantities in addition to Reynolds number.

5 Additional performance tests should be made with pumps of different design, especially with pumps of higher specific speeds. Such tests could be made on a much more economical basis now, since the pertinent variables and trends are established. Effects of changes in design should be systematically studied.

Acknowledgment

The study reported here represents an example of academic-industrial co-operation, which was sustained by the active interest of the administrative officers of Lehigh University and of the Ingersoll-Rand Company in this work. In this connection the author is especially indebted to Mr. W. M. Stanton of Ingersoll-Rand and to Prof. H. Sutherland of Lehigh University. Intimately connected with the technical phases of the work were Messrs. A. P. Brocklebank and H. Hornschuch, to whom the author wishes to express his particular appreciation. Mr. Ming Lung Pei was responsible for a great deal of analytical work. Thanks are due to a considerable number of other associates connected at various periods with this work and to the loyal co-operation of the staff members of the Hydraulic Laboratory of Lehigh University.

Discussion

N. Tetlow.[3] The writer would like to congratulate the author on his paper, which provides an outstanding contribution to our knowledge of the viscous-flow characteristics of the centrifugal pump. He would like to endorse the author's statement that previous investigations have provided only temporary methods of approach; they have, however, served a very useful purpose indeed pending the accumulation of knowledge which permits a more scientific study.

Past contributions to engineering societies, and in published works, have always given rise to a good deal of discussion in which the theoretical principles associated with the Reynolds number of a pump have been ventilated at considerable length. All previous treatment of this subject, however, has been purely academic and has not been supported by practical evidence.

The researches now recorded by the author have done much to fill in this missing information and permit us to make a more accurate assessment of the influence of Reynolds number on performance. The writer would go so far as to say that this paper provides the first convincing evidence that he has seen in which the influence of running speed is demonstrated.

It is encouraging to learn from the paper that the author proposes, at a later date, to reproduce the results of his observations in a form which will lend itself more easily to the solution of practical problems. It is hoped, therefore, that some suggestions regarding the method of approach will prove helpful.

The method adopted by the author to correlate an almost bewildering series of observations is to plot, in the Reynolds curves, only the pump performances corresponding to maximum efficiency. To do this he has suggested that the locus of the maximum-efficiency point on the head-capacity curves, follows the law $Q/\sqrt{H}$ = constant.

It will be seen from the paper that this is a reasonable method of approach, and it has induced the writer to examine, from this viewpoint, the information in his own possession. This examination suggests that the path of the maximum-efficiency point on the head-capacity curves corresponds more nearly to constant specific speed than to constant $Q/\sqrt{H}$.

As an example, the curve in Fig. 18, taken from a paper[4] by the writer, and plotted on the basis of imperial gallons per minute, shows the characteristics of an 8-in. single-stage volute pump when handling oils of different viscosities. On these curves has been superimposed the constant-specific-speed line $\frac{G_1}{G_2} = \left(\frac{H_1}{H_2}\right)^{3/2}$ which, it will be noted, corresponds with a fair degree of accuracy to the points of maximum efficiency. A study of the examples in Fig. 13 of the author's paper, shows a similar trend. It is suggested, therefore, that the use of constant specific speed not only corresponds more nearly to observed results but, for reasons which are given later in this discussion, may also have other advantages when the available information is applied to practical problems.

The writer has also analyzed the results of a number of viscous-flow tests in a series of curves in which head and efficiency performances are plotted against N_d in the manner suggested in the paper, but now on the basis of constant specific speed. The available number of tests is limited, but they do suggest that a reasonable measure of agreement may become possible, as indeed it should, if pumps of similar specific speeds are compared. There is a fair amount of "scatter" but not more than one might expect, bearing in mind the large number of variables and the ever-present possibility of experimental errors. It is suggested, therefore, that a more complete investigation on this basis may prove illuminating.

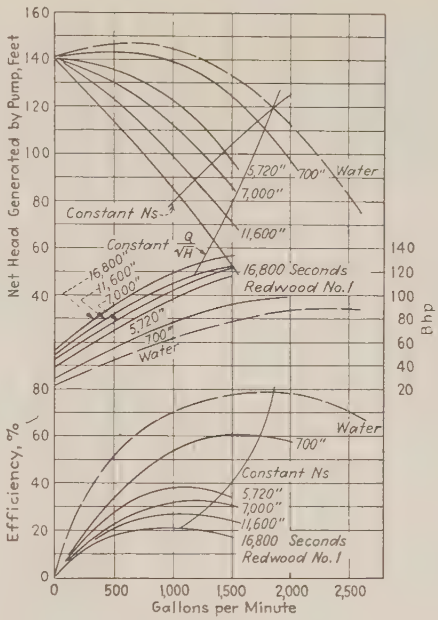

Fig. 18 Test Characteristics of 8-In Volute Pump Handling Viscous Oil Products

If the writer's preliminary observations on this subject are supported by further investigation, then it should be possible to prepare a complete family of Reynolds curves to cover all variations in speed, size of pump, viscosity, etc., each curve corresponding to a particular specific speed. In this event, the advantage of using the constant-specific-speed line instead of the constant $Q/\sqrt{H}$ line proposed by the author will become evident. Given any duty to be performed, once the running speed is determined, it will then be possible to calculate the specific speed, a figure which will establish immediately the appropriate correction curve to be used.

Such a series of Reynolds curves to cover the usual range of specific speeds would provide a concise means of applying the results of the author's tests to practical problems. By their use the size of pump most suitable for the duty required could be established, the problem being simplified by our knowledge that the specific speed will be constant whether handling a viscous fluid or water.

It would be possible also to superimpose on the Reynolds curves the maximum-efficiency duties, when handling water, for any range of pumps available. Not the least advantage of this method of approach is the fact that maximum possible efficiency when handling the viscous fluid could be assured automatically.

The writer would like to have studied this method of approach more carefully, but the combination of postal delays and closing date for communications does not permit this. It does appear possible that there may be a reason, based on fundamental principles, why the constant-specific-speed line should correspond so nearly to maximum-efficiency performance. He would like the author to approach the problem from this angle and would be grateful for any observations he is able to contribute.

The writer has only one criticism to make regarding this

[3] Consulting Mechanical and Electrical Engineer, Manchester, England.

[4] "A Survey of Modern Centrifugal Pump Practice for Oil Field and Oil Refinery Services," by N. Tetlow, Proceedings of The Institution of Mechanical Engineers, vol. 150, 1943, pp. 121–134.

admirable contribution to engineering science. The value of the paper would have been increased enormously if the author had found it possible to append a list of the symbols and the units of measurement used throughout the paper. When dealing with such measurements as viscosity and Reynolds number, it is so easy to introduce an element of confusion that it is hoped he will find it possible to include this additional information in his closure to the paper.

A. Hollander.[5] The author has made an important contribution to a subject which is badly neglected by the manufacturers of centrifugal pumps. It is regrettable that owing to the severe limitation of the length of the paper, some pertinent data were obviously omitted, thus preventing the examination of some aspects of the problem which are different from those of the author or held for future papers.

For example, the writer posed the question some years ago whether the affinity law broadened to include viscous liquids but narrowed down to head and capacity so as to exclude brake horsepower and efficiency and with these the external losses, is valid or not for the same Reynolds number. According to this law, taking a single impeller and having available the complete head-capacity (QH) curve for a given constant speed (N) and viscosity (ν) from shutoff to zero head, for another speed (KN), another complete head-capacity curve could be figured point by point for a viscosity ($K\nu$); the corresponding points of capacities would be KQ and of heads K^2H. Comparing the through-flow at any point of the impeller, the velocity diagrams should be similar for the two speeds of operation. The Reynolds numbers at different points of the impeller or case will vary for a single test point, but for the second test at a different speed and the same viscosity-speed ratio, they should vary the same way, because at any given point of the impeller or case the Reynolds numbers are identical for the two tests at corresponding capacities. For instance, if we have the test of pump IL11 at 2330 rpm and 10,000 SSU, we could figure the head-capacity curve for 1750 rpm, that is, $^3/_4$ speed for 7500 SSU, using as corresponding points $^3/_4$ capacities and $^9/_{16}$ heads. This is the only viscosity for which the foregoing test could be used at 1750 rpm. Going up in speed to 3500, the same test would give a performance for 15,000 SSU viscosity.

This prediction of the complete head-capacity characteristics from a test at a single speed for other speeds and viscosities, which have the same N/ν ratio (that is, the same Reynolds number) would be very desirable even if the best efficiency points were not at corresponding points due to a different change in the external losses. Unfortunately, the published data of the author (Figs. 14 to 17) show only one point of the performance curves at which $\frac{Q_0}{\sqrt{H_0}}$ is the same as the $\frac{Q_w}{\sqrt{H_w}}$ for the best efficiency point for water. Now the affinity law is valid for water (see Fig. 8, where the points coincide), so that

$$Q_{w1} = K_q N_1 \text{ and } \sqrt{H_{w1}} = K_h N_1$$

For any other speed

$$Q_{w2} = K_q N_2 \text{ and } \sqrt{H_{w2}} = K_h N_2$$

so that

$$\frac{Q_1}{\sqrt{H_1}} = \frac{Q_2}{\sqrt{H_2}} = \frac{K_q}{K_h} \text{ const}$$

means that corresponding points are plotted. What the author's modified affinity law tells us is, that for a given Reynolds number the H_0/H_w points should coincide. This is true for pump IL21, Fig. 15, showing a single line for this curve, and except for a short section for IL22, which shows about a 3 per cent deviation between $R_D = 10^4$ to 2.5×10^4.

The smaller pump IL11 shows a similar, and IL12 a somewhat greater deviation. Of course it would be instructive to see whether or not these deviations remain so small at other $\frac{Q}{\sqrt{H}}$ values for the whole performance curve. This would eliminate any doubt whether the deviations, amounting to something like ± 4 per cent, are due to experimental difficulties in a small region, which might arise if the flow at some point would be going through a Reynolds range between laminar and turbulent, where the repetition of a test point even in plain pipe flow is difficult. Also, it would be desirable to make tests with a much greater speed range, which would permit a similarly greater viscosity range for verification.

If, because of secondary effects, the affinity law were not fully valid, the second question that is posed is whether it would not be valid for geometrically similar pumps operating at speeds and viscosities giving the same Reynolds number against the same heads. In this case the speeds would be inversely proportional with the sizes and the viscosities proportional with the speeds. The velocities (peripheral, relative, and absolute) for corresponding points would be identical at the same heads, so that the corresponding flow rates would be proportional with the areas (square of the size ratio). Having made a set of tests at different speeds and viscosities with a single pump, we could predict the performance of a similar pump of size ratio (K_D) for speeds and viscosities ($1/K_D$) times the test figures.

A confirmation of these laws, which follow from a dimensional analysis, would leave as the only criterion for the prediction of the performance of similar pumps for viscous liquids the equation

$$\frac{K^2_D K_N}{K_\nu} = \text{const}$$

where K_D is the size ratio, K_N the rpm ratio, and K_ν the viscosity ratio.

It should be noted that, strictly speaking, the foregoing considerations are only valid if the leakage through the wearing rings is neglected; otherwise the zero point of the abscissa should be shifted by the amount of leakage, which differs for every head, even for a single Q-H curve at constant speed and viscosity. However, it seems that disregarding this leakage is permissible, because it is a relatively small percentage of the total flow (except near the shutoff point) and particularly for higher viscosities.

Lacking a reasonable theory, the reduction of Q and H at a constant speed and increasing viscosities can be determined only by experiments as the author conducted them. Even with a consistent design of a line, these should be repeated for different types, that is, pumps of different specific speeds over a wider range. Different hydraulic designs, such as single- and double-suction pumps, should come under different headings as primarily they should be compared between themselves, and only secondarily should the comparison be made between the two lines (a) for the same duty (Q, H, N) as the author did, and (b) for the same flow lines in the impeller, that is, taking one half of the capacity of the double-suction impeller, because it consists of two single-suction impellers pasted together with the central bridge omitted well below the outside diameter. For a given duty and particularly for low-specific-speed pumps, the single-suction pump should give better performance, and this even more pronouncedly for small sizes (lowest Reynolds numbers).

Going to the next step, that is, predicting at least one important point of the performance at different viscosities, the writer

[5] Associate Professor of Mechanical Engineering, California Institute of Technology, Pasadena, Calif. Mem. A.S.M.E.

would suggest for this, instead of the point of best efficiency, the point of maximum water or oil horsepower. This is a reasonably definite point, undisturbed by external friction losses, such as disk or ring friction, but dependent substantially upon the flow through the impeller and case only.

This approach would be in line with the author's laudible start of trying to separate the external losses, which could therefore be deducted from the brake horsepower. This figure, compared with the water or oil horsepower, would show the effect of viscosity on the flow or on the hydraulic efficiency of the pump.

The hesitation of the writer to use water or oil horsepower is due to the lack of an acceptable term, which should rightly be "output horsepower." After all, the pump is lifting in unit time a certain weight of liquid to a given height, and the product of these, times a constant, while regularly called "water horsepower," because water is the pumped liquid, is really output horsepower for any liquid.

It seems that for the two complete tests shown, the points of maximum output horsepower are on a line of

$$\frac{Q}{\sqrt[3.3]{H}} = \text{const}$$

Other tests indicate a different exponent of H, as one would expect from greatly varying designs.

These points of maximum output horsepower are for water not far from the best efficiency point, and if they separate further at greater viscosities it is a sign of a different change in the hydraulic and external losses. Any effort to obscure the condition with a single curve for the best efficiency point, as was always done, seems to give a finality to the results which is not warranted and would retard the more fundamental examination that is called for. The omission of the output-horsepower curve from the standard pump-performance curves which show head, efficiency, and brake horsepower as a function of flow rate at constant speed, is even for water objectionable, because it does not show some important characteristics of the pump which would lead to a more intelligent appraisal of its worth.

The value of the different maximum output horsepowers as a function of viscosity is really the function that the designer or user wants, after the QH function for maximum output horsepower is known. With the latter it gives the relative change of Q and H with viscosity. With the external losses determined for different viscosities, the hydraulic efficiency could be figured besides the over-all efficiency as was previously done to give a complete picture. Following this through for different types from zero to shutoff head would possibly shed some light on the very irregular flow at partial and overcapacities, not only on the maximum-output points hitherto compared. With this knowledge then, it might be possible to design better pumps for high-viscosity liquids, which oddly enough was successfully attempted in Professor Daugherty's first and still classical tests (1).

It might be argued and correctly so, that these notes are merely suggestions for a further program rather than criticism of the present paper. It is only fair to add that the author did make a valuable contribution and in more than one direction struck new paths, particularly in calling attention, to the writer's knowledge for the first time, that the wearing ring friction is a major external loss, which cannot be lumped together with the disk friction as a small additional loss.

L. F. Moody.[6] The effect of the viscosity of the fluid on pump performance has remained a problem without a satisfactory answer, and it has not been possible for pump designers to predict with any assurance the modification of water performance to be expected when pumping oils or other fluids. The existing data have been limited to more or less isolated tests and few comparisons under controlled conditions have been available. When looking for the effect of the change of a single variable, reliable conclusions can hardly be deduced from tests on separate pumps, for example, or from any tests where other variables do not remain identical. It is believed that the author's research is the first systematic study of the problem under carefully controlled conditions covering a wide enough range to establish definite conclusions.

The paper provides a wealth of data although, as mentioned by the author, further analysis is still needed to reduce the experimental results to readily usable form. The test data are now at hand, but the complex nature of the problem does not make it easy to apply the results to any specific case. It would be a valuable addition to the material included if sectional views of the pumps tested could be appended to the paper, as this information is necessary for complete analysis.

The method of analysis adopted in the paper is logical and sound, namely, the plotting of the performance with respect to a Reynolds number, which reduces the results to dimensionless form. Several useful forms of Reynolds number are used, one of which, R_D, depends upon the impeller speed and reflects directly the effects of disk friction and clearance friction, while other forms such as R_S and R_P reflect more directly the flow velocities. The plotting of the proportional-energy loss $\frac{100 - e}{100}$, or as the writer would prefer to express it, $1 - e$, (using e as a fraction rather than a percentage) is also a reasonable procedure.

With these data available, it would seem possible to arrive at some simple empirical rule which would permit us to modify the efficiency and head given by water performance to apply to oil, at least for light oils, over a moderate range of viscosities. The writer has found it difficult to read the small-scale logarithmic plottings, in the effort to find a satisfactory functional relation. Perhaps a function of some such form as the following may serve the purpose

$$e_W - e_0 = K(1 - e_W)\left(\log \frac{R_{DW}}{R_D}\right)^2$$

in which e_W = efficiency for water (as a fraction, not a percentage); $R_{DW} = R_D$ for water; and K is a coefficient, depending upon specific speed and perhaps other characteristics of the pump.

It is hoped that the author will be able to continue his own study of the problem, and to give us an easily applied rule which would serve at least as an approximation close enough for practical use.

The fact that the curves flatten out in the region of water performance, so that the behavior then practically ceases to be a function of Reynolds number, confirms the point of view expressed by the writer in the past, namely, that when handling water, the flow in usual sizes of pumps of normal specific speeds, and still more clearly in hydraulic turbines, falls in the zone of practically complete turbulence. Accordingly, the efficiency for water operation should be practically independent of the head, and be a function merely of the relative roughness of the surfaces exposed to the flow.

The research represented by this paper is an example of systematic hydraulic experimentation at its best, and care and thoroughness are evident throughout the undertaking. The results are valuable contributions to our knowledge.

R. L. Daugherty.[7] The author has investigated centrifugal-

[6] Professor of Hydraulic Engineering, Princeton University; Consulting Engineer, Worthington Pump and Machinery Corporation, Harrison, N. J. Fellow A.S.M.E.

[7] Professor of Mechanical Engineering, California Institute of Technology, Pasadena, Calif. Fellow A.S.M.E.

pump performance with oil viscosity as high as 10,000 Saybolt seconds, which is a viscosity of 2200 times that of water. This is probably about as high as there is any practical need for going.

The writer carried on extensive investigations in this field and under the same range of viscosity in 1924 and 1926, and the results were published in two bulletins.[8] Those investigations showed very clearly that capacity, head, and efficiency all diminish with increasing viscosity and that the effects were more noticeable with small pumps than with large ones.

Another factor which must certainly have an influence upon the variation of pump performance with viscosity is the specific speed. The author has made a start in presenting this phase of the subject. However, neither size nor specific speed will tell all the story. Thus in Fig. 19, which the writer has replotted from his earlier data, may be seen the difference in the performances of two pumps of the same size and of substantially the same specific speed when operated with fluids of different viscosities. It is seen that the design, which is more efficient for a fluid of low viscosity, is less efficient for a fluid of high viscosity.

The author has correlated his data on the basis of Reynolds number, but with a separate set of curves for each individual pump. If the rpm were also constant the only variable would be kinematic viscosity such as the writer has used in Fig. 19. Thus in Fig. 19, herewith, two viscosity scales have been added, since viscosity is there the only variable entering into the Reynolds number. One of these viscosity scales is that for Saybolt seconds and the other is kinematic viscosity in centistokes. The former is used here because of its extensive employment in industry, but the latter is a scientific unit with more physical meaning. Thus since at 68.4 F the absolute viscosity of water is 1 centipoise, and its kinematic viscosity is 1 centistoke, the viscosity given in either centipoises or centistokes is at the same time an indication of the viscosity relative to water at that temperature.

The Reynolds number is computed by a formula in which N is revolutions per minute and d_2 is the impeller diameter in feet, while the kinematic viscosity is expressed in square feet per second. This viscosity is equal to the viscosity in centistokes multiplied by 0.00001076. The writer has adhered to this combination because it is the same used by the author, but in the writer's opinion it would be more convenient to compute this by $\dfrac{16.93\ ND_2^2}{\text{centistokes}}$ where D_2 is the diameter of the impeller in inches.

The specific speed has been computed as

$$N_s = \frac{\text{rpm} \times \sqrt{\text{gpm}}}{H^{3/4}}$$

This is obviously the same expression which the author has used for his values, but it is well to state this specifically since cubic feet per second or other units are often used instead of gallons per minute. In the case of a double-suction pump, it seems preferable to use one half of the total pump capacity in such a calculation, but the author does not indicate whether he has followed that practice or not in the values which he gives.

In Table 1 of the paper it would be desirable to define the meaning of the symbols there used since they are not obvious. In connection with Equations [2a, b, c, d], it should be stated that N is revolutions per minute, that d_2 is the diameter of the impeller in feet, although in Fig. 11, D is used for the same value.

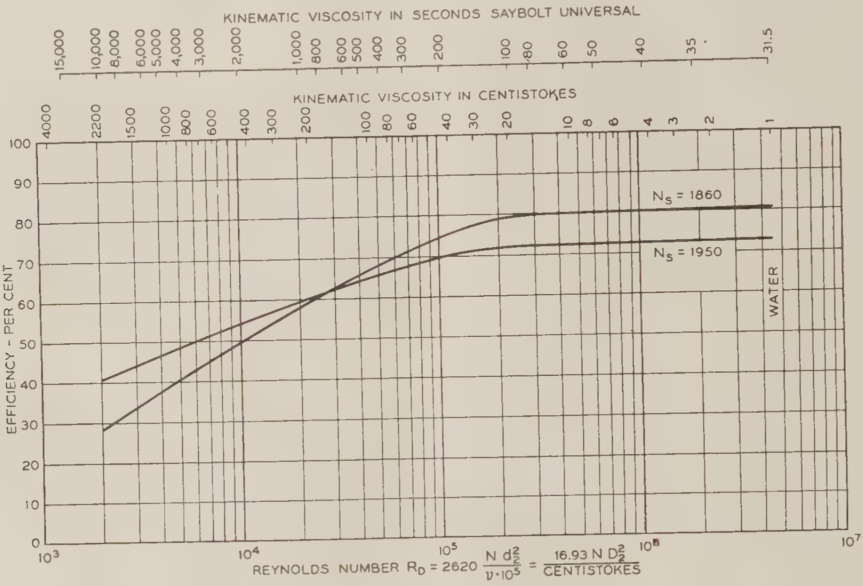

Fig. 19 Performance Curves for Two 8-In. Pumps
(Impeller diameter = 13.5 in.; 1450 rpm.)

It is to be hoped that the author or others may continue to obtain data on centrifugal-pump performances with different viscosities and with a range of sizes, specific speeds, and other design features so that eventually a comprehensive chart may be drawn up which would be a reliable guide for any combination of conditions. However, it is difficult to generalize with only a limited amount of data.

O. H. Dorer.[9] The author's contribution toward the solution of the problem of viscosity effects in centrifugal pumps indicates

[8] Refer to Author's Bibliography (1); an earlier bulletin was published in 1924.

[9] Consulting Engineer, Worthington Pump and Machinery Corporation, Harrison, N. J. Mem. A.S.M.E.

a method of attack attempted by the writer some time ago and since abandoned. By this is meant the head corrections based upon percentage of water performance, and some classification numbering system similar to Reynolds number by using impeller diameter and finally unit speed (n), which is a function of impeller diameter.

Subsequently, a formula for

$$R_N = \frac{14{,}100G^{1/2}}{\gamma} H_v^{1/4}$$

was adopted in which G = gpm, H_v = velocity head, γ = viscosity in centistokes. It is seen that the troublesome size factor has disappeared, and this is possible through substitutions in

$$Q = 0.785\, D^2 \sqrt{2gH_v}$$

the usual pipe formula, where H_v is the head creating the velocity.

In the centrifugal pump the velocity creates the head, so we can use a similar value for over-all Reynolds number. However, since the conception of H_v is from an original velocity determined not by the developed head, but by an internal head which overcame all head losses in the pump, the internal rather than the developed head is used. The internal head corresponds to input horsepower with a deduction for disk friction, bearing and stuffing-box loss. At zero capacity the recirculation capacity is considered in calculating internal head from the input power.

Of the input power, that part overcoming disk friction, bearing and stuffing-box loss is not a direct hydraulic-flow loss. A determination of this loss was made by placing solid dummy impellers in the pump casing having all details like the real impeller, except that the outer band normally used as discharge passage gives extra disk loss. Corrections were determined by extending the

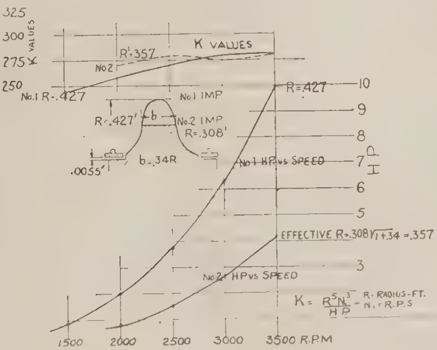

Fig. 20 Water Disk Horsepower of Dummy Impellers

(10-hp dynamometer used; tests include bearings, stuffing boxes, and sealing rings.)

dummy to a rounded-nose affair, as illustrated in Fig. 20 of this discussion. (Water) disk horsepower follows the form of

$$\text{Hp} = \frac{R^5}{K} N_1^3$$

where R = radius, ft; N = rps; K averages 280.

Zur Nedden[10] found with simple disk tests

$$\text{Hp} = \frac{N_1^{2.9} R^{4.9}}{420} \text{ (average value)}$$

However, Gibson and Ryan tests are reported at

$$\text{Hp} = \frac{N_1^{2.9}\, R^{4.9}}{330}$$

Both of these are simple disks, polished, and in rough cast-iron surroundings; and neither of them can be considered as reflecting all the conditions surrounding impeller surfaces, ring, joints, etc. Hence their low values of horsepower are not considered to be applicable to centrifugal pumps.

In order to arrive at proper wall pressures, the dummy impellers were tested under pressures at mid-radius, as recorded by the actual impeller during its operation.

Disk horsepower bears a relationship to specific speed, a low specific speed having relatively more of this loss than higher-specific-speed pumps. The build-up of disk horsepower with viscosity may be very high on a low-specific-speed pump.

While ring-leakage loss is reflected in the net output, it is proper to allow for it in obtaining H_v. Practically, for water performance, H_v may be determined from H_a (actual head) by dividing it by the hydraulic efficiency, here defined as efficiency, not including disk horsepower. In any reasonable size pump ring leakage[11] is a small percentage; it may be neglected.

However, with viscous oils this ring leakage decreases to some extent, and in small pumps its decreasing rate could improve the oil head obtained, above water performance.

The basis for considering effects of viscosity states: (*a*) The increase in power input, corrected to unity specific gravity, is due to increased disk friction, see Fig. 23 of this discussion; (*b*) the decrease in head is due to several features, i. e., the frictions in the passages, the lag in attaining velocity imparted by the blades of the wheel, and finally, the poorer efficiency of velocity-head conversion within the pump.

While equal-size pumps are built with various spiral velocities, some relatively high, others relatively low, for similar specific speeds, it is clear the friction in the large-area spiral will not build up as fast with increase in viscosity as is the case in smaller-area spirals.

A similar situation applies to impeller passages; fewer vanes infer larger hydraulic mean radius and lesser frictions.

With both elements designed for low velocities to reduce frictions, there is an adverse effect in the hydraulic efficiency, and of velocity-head conversion. The problem in viscosity then boils down to which element is most destructive. It will be shown that frictions are more detrimental than the destruction of velocity-head efficiency in some designs of pumps.

Manifestly, each of these elements has a Reynolds number, and various rates of friction loss or head destruction; and while we apparently have a Reynolds number for the particular pump, there does not appear to be an over-all Reynolds-number system applicable to the range of pumps that may be used for viscous-oil applications in a manner similar to the pipe problem.

In this connection, the theory of action in a centrifugal impeller poses another problem. If all head is developed entirely through velocity, H_v is directly determined. However, some of the head is composed of centrifugal force which is at a maximum at the shutoff and at a minimum, at large flows. In fact, when centrifugal force is absent, cavitation begins. Principal formulas for centrifugal force are given as follow

$$H = \frac{YU_2}{g}(YU_2 - W) = \frac{\text{input hp} - \text{disk hp}}{0.1135\,(Q + \text{ring leak } Q)} \quad ..[20]$$

$$\text{Per cent centrifugal force} = 100 \times \left(\frac{H}{1.22\, N_1^2 R^2} - 0.5Y^2\right) \quad ..[21]$$

[10] "Influence of Disk Friction on Turbine-Pump Design," by F. Zur Nedden, Trans. A.S.M.E., vol. 37, 1915, pp. 83–107.

[11] Ring leakage was $2^1/_8$ per cent for the 4-in. pump in which the dummy impeller was tested, and is independent of speed, for a given impeller.

where

U_2 = peripheral velocity, fps
W = horizontal backward component in usual velocity diagram, neglecting contraction
Q = volume delivered, cfs
R = radius impeller, ft
N_1 = revolutions per sec
H = impending head, ft

With the centrifugal-force element deducted, H_v is of a lower value and the viscosity would not affect centrifugal force except through additional lag of vane action on the fluid. In all following comparisons it has been assumed that no lag occurs.

The 8-in. Mather and Platt pump-head results have been investigated for viscosity at three rates of flow, Fig. 21 of this discussion. The sudden bump in the curve may be caused by change of oil, even though the viscosity scale is continuous. It is suspected that the type of oil has some influence. Here the hydraulic efficiencies have been calculated on the assumption that all generated head comes from velocity conversion. At the top of the sheet a series of n exponentials indicates variation with constant apparent Reynolds number.

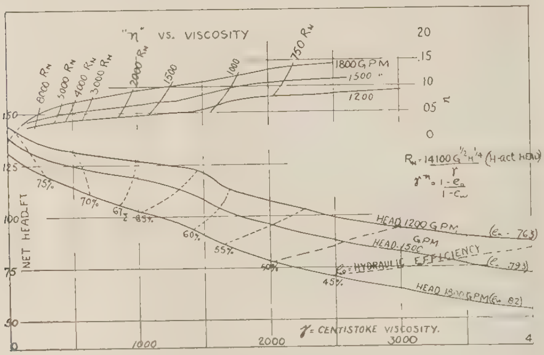

Fig. 21 Pump-Head Results on Mather & Platt 8-In. Pump

Pipe frictions may be compared where viscosity is the only variable by an exponential n of viscosity; it is nearly 0.20. For head conversion in the centrifugal pump, this same exponent of viscosity is seen to be variable and considerably below 0.20.

The low n values of head, compared to frictional n values, infers that the head conversion which is the major part of H, does not decrease as fast with increase of viscosity as frictions increase. With the very heavy viscosities, the increase in n infers greater destruction in conversion of velocity to head than at low viscosities.

In order to substantiate these facts, the frictional slopes for impeller and spiral were calculated and allowed for, as well as the centrifugal force, and the remaining values represent hydraulic efficiency of velocity-head conversion.

$$\text{Friction slope} = \frac{2.7\, f H_v^{5/4}}{G^{1/2}}$$

through substitutions for size indicated in an earlier part of this discussion.

Considering the centrifugal-force element we can write

$$1 - \frac{2.7 f H_v^{5/4}}{G^{1/2}} = e_v = \frac{H_a - \text{CF} + F_r}{H - \text{CF}}$$

H_a = actual developed head
CF = centrifugal-force head

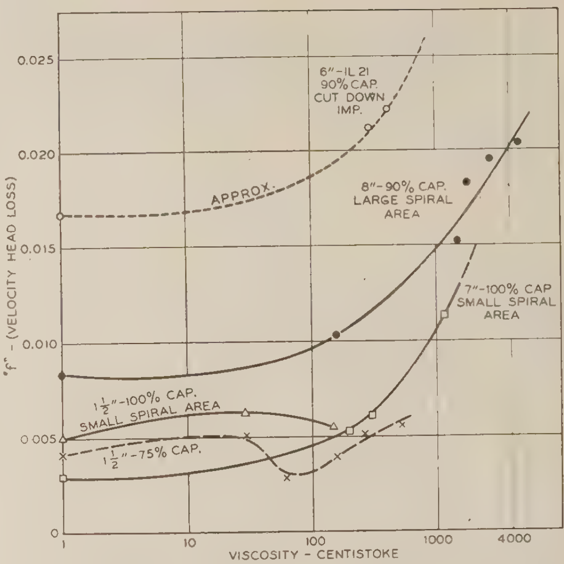

Fig. 22 Frictional Slopes for Pump Impeller and Spiral

F_r = friction loss in spiral and impeller
H = impending head
C_v = velocity-to-head conversion efficiency factor

Here f is similar to the friction factor of pipe calculations, but refers specifically to a friction factor of velocity-head conversion.

Fig. 22 of this discussion gives the results of such an analysis and confirms that velocity-head conversion is not destroyed as rapidly in some designs as friction builds up. The small-spiral-area pumps are more efficient as water pumps having low f values.

The small $1^1/_2$-in. pump seems to have better f values at 75 per cent capacity; however, this illustrates the ring-leakage effects which have been neglected, and which bear a larger percentage to output than is the case in large pumps. The decrease in leakage with increase of viscosity in the small pump is responsible for the apparent improvement in f values.

Confirming that friction and velocity-head destruction of head on viscous oils do not proceed at equal rates, the 8-in. and 7-in. pumps are compared (Table 3 of this discussion) on a common flow, and viscosity, viz. 1500 gpm at 1000 centistokes viscosity. The velocity through the spiral of the 7-in. pump is about $2^1/_4$ times that of the 8-in. pump. (The IL-21 pump is shown at 1050 gpm as 930 centistokes).

TABLE 3 COMPARISON OF 7-IN. AND 8-IN. CENTRIFUGAL WITH 6-IN. IL21 PUMP

	7-in. pump	8-in. pump	6-in. IL21 pump
H water	165	135	80
H oil	108.5	133	$62^1/_2$
Per cent head loss	34.2	16.2	21.9
Hydraulic efficiency, water, per cent	91.3	77.3	81.0
Net efficiency, water, per cent	85.0	73	80
Velocity efficiency, water	90	68	73.3
Velocity efficiency, oil	63.5	59	57.0
Friction, water	1.75	1.0	1.0 (estimated)
Friction, oil	23.8	13.2	9.8
f_w	0.00323	0.0119	0.0168
f_o	0.0118	0.0152	0.271
m exponential	0.302	0.303	0.46
Centrifugal force, ft	49.0	57.0	32.0 (w estimated at 10)

While the friction losses increased by an amount equal to 13.4 per cent of the developed water head, the loss in converted

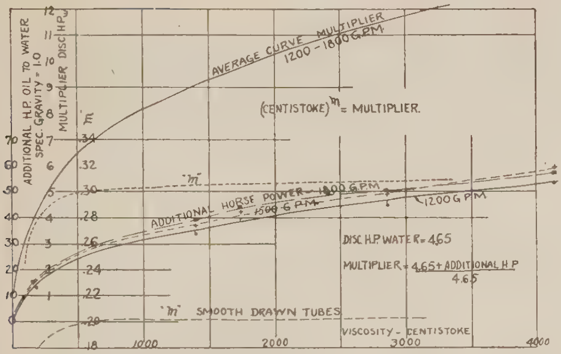

FIG. 23 EFFECTS OF INCREASING VISCOSITY ON PUMP PERFORMANCE

velocity head increased 21 per cent for the 7-in. pump. On the other hand, the 8-in. pump increases are 9.05 per cent and 6.6 per cent, respectively, for these items. The high f_w value of the IL21 pump is undoubtedly due to the large cutdown of impeller, resulting in a relatively long space between impeller and spiral. This space does not appear to affect results as badly on viscosity as in the case of the 7-in. pump, but more so than the 8-in. pump.

The changes in rates by which each element behaves in the different types of designs appear to nullify a universal application of over-all Reynolds numbering system with head and efficiency correction factors applied to the water performance.

The m exponentials affecting power are likewise variable; some high-head per stage pumps showing as low as 0.18. This suggests that rapidly moving disk surfaces create a film of apparently low viscosity or heating at the surfaces.

In conclusion, it appears necessary that more test results be provided to develop acceptable designs for best oil performances; and specific methods of calculation then are a matter of choice.

AUTHOR'S CLOSURE

The discussions submitted have contributed greatly to the further clarification of the complex problems involved in analyzing the influence of viscosity on the behavior of centrifugal pumps. The discussers have raised relatively few controversial points and have contributed instead from their own experiences valuable observations and suggestions for future work which need little additional comment. The author indicated at various times in the paper that the exploitation of the test data was only partly completed. Considerable information should be gained from further critical analysis of the individual performance curves with respect to separation of "external" from so-called "internal" losses, by comparisons with results of other experimenters, and by investigating the influence of such findings on established design procedures. The present paper was intended primarily to establish a common basis of discussion on the strength of extensive experimental evidence, to clarify the basic nature of the various losses, and to estimate their relative influence. The author feels greatly reassured since his line of attack was not seriously questioned. The work may now be continued toward eventual correction curves of more general validity.

A few remarks are in order to answer some specific problems raised by the various contributors. Mr. Tetlow brings up the question whether or not the specific speed N_S should remain constant regardless of viscosity: Curves drawn on the basis of N_S = const (i.e., $\frac{Q}{H^{3/2}}$ = const for a given pump and a given speed) in the head-discharge curves give maximum efficiency points for high viscosities better than the author's method of keeping $\frac{Q}{\sqrt{H}}$ constant. Naturally various methods of defining normal capacity and normal head were discussed and tried during the analysis of the data and the present method was adopted essentially for practical reasons. Up to relatively high viscosities the efficiency corrections obtained by either method are practically identical. Applications where the efficiencies drop below 30 per cent or 25 per cent are not expected to be numerous. The efficiencies can be kept above these values by changing the type or the design of the pumps (see Professor Daugherty's example).

It seems contrary to experience with fluid friction that a single law should be valid from the range of "complete turbulence" through the turbulent transition zone into the completely laminar state of the "through flow." While reduced capacity and head result in a corresponding shift of the peak horsepower output, the higher rate of increase in the so-called external losses, especially disk and ring friction, will tend to produce a slower corresponding shift of the peak efficiency. The author agrees with the discussers who have pointed here to the need of further analysis so that the influence of the internal losses may eventually be separated from that caused by external losses.

For the present the method adopted seems the most useful one, since the assumed proportionality of Q and $\sqrt{H}$ enables the engineer to calculate these values for small changes in speed N and impeller diameter d_2, in accordance with established procedures derived from the affinity laws. It may also be called to mind that the usual concept of specific speed is associated with similar flow conditions in a given pump regardless of speed, resulting in the proportionality of speed to Q and $\sqrt{H}$ with constant proportionality factors. This precludes any influence of the viscosity on the flow conditions. If with increasing viscosities such influences result in a marked change in these proportionality factors, the geometric similarity of the through flow is disturbed though the boundaries and the speed may remain fixed.

For all practical purposes then, the pumping process is changed and it is hard to conceive of specific speed remaining constant under these conditions. The pump type may still be classified, however, by its water-specific-speed, and correction curves may be drawn on that basis. Since the change in the specific speed on the basis of $Q = K\sqrt{H}$ is inversely proportional to the discharge correction factor, the resulting increase in the specific speed remains relatively small. Finally, it may be added that the increasing external losses also have a certain effect on the specific speed, since they affect the location of the maximum efficiency point.

The exact significance of specific speed therefore is not too clear in connection with the problem of viscous influences on pump performance. It represents a classification number for normal water performance, where it remains constant for a given type of pump, since flow conditions remain geometrically similar regardless of speed and diameter. This similarity is due to the almost complete absence of variations in the viscous influences and to the minor variations of the external losses. This similarity will break down if the viscosity increases greatly and it seems reasonable to acknowledge this fact by a change in the specific speed.

The preparation of correction curves is not greatly affected by the definitions and correlations of normal discharge and normal head. The author agrees, however, with Mr. Tetlow in the desirability of further analysis and of theoretical investigations on the foregoing question.

Professor Hollander and Professor Daugherty have inquired into the definition of specific speed concerning single-suction and double-suction pumps. The author calculated the values of N_S

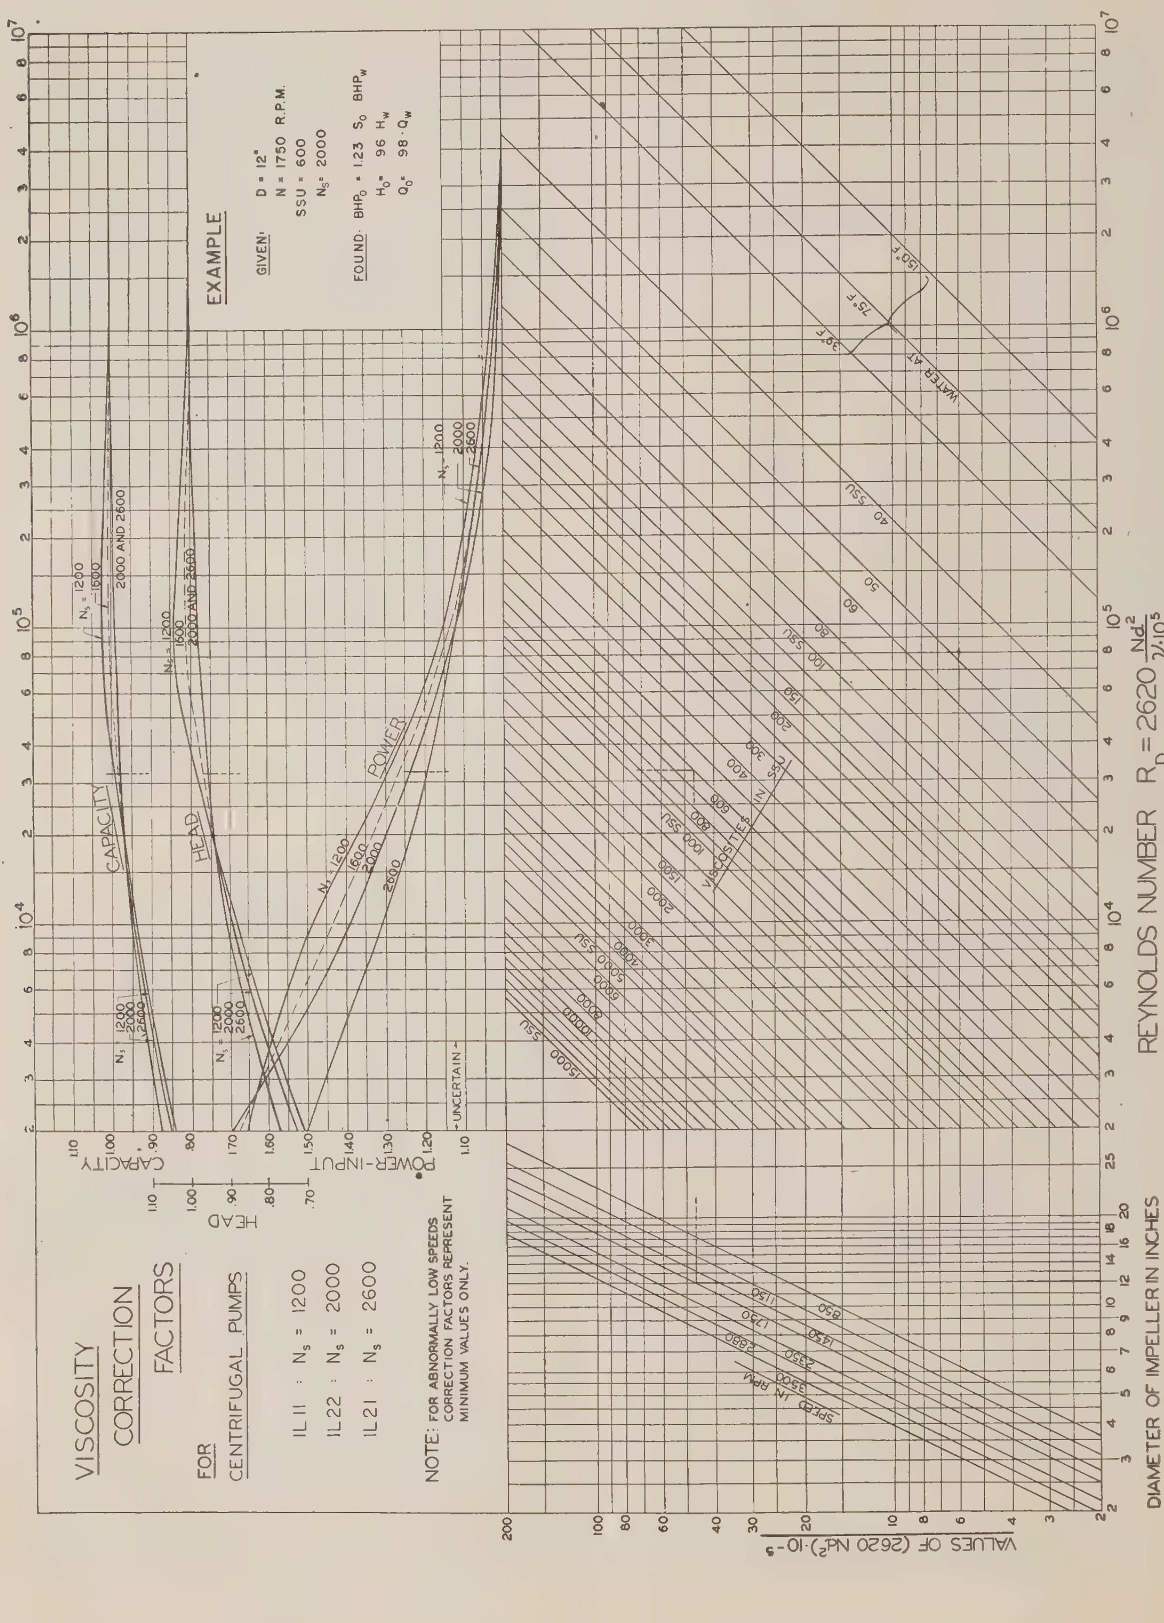

FIG. 24 GRAPHICAL METHOD OF DETERMINING R_D

using total discharge Q in gpm, H in ft, and N in rpm. It is believed that the distinction between single- and double-suction pumps need not be insisted upon in connection with the problem in question. Using only one half the capacity for a double-suction pump to obtain the characteristic specific speed is in order whenever problems concerning entrance conditions and especially cavitation phenomena are investigated. For the problem under discussion it is doubtful whether a better comparison to single-suction pumps would be obtained except for very high specific speeds. If a double-suction impeller were to be replaced by two single-suction impellers, the hydraulic losses would probably be changed very little; however, the horsepower input for each impeller would have to be corrected for greatly increased external losses, since disk- and ring-friction losses would be doubled. The corresponding decrease in the efficiency would offset the correction of the specific speed. Such corrections for external losses for these equivalent impellers could not be made in the present state of knowledge.

For water performance disk- and ring-friction losses form usually only a small part of the total losses, which are essentially hydraulic or internal losses there, so that such corrections would be of negligible order of magnitude. For these reasons it seemed preferable to state the specific speeds for the double-suction pumps (IL21 and IL22) on the basis of their full capacity. Further light on this question must come again from a possible separation of so-called external and internal losses.

Professor Hollander has given an admirable statement and summary of the consequences of the viscous changes on the affinity relations and points out the direction toward the considerable work ahead in this field. It is clear that the conventional thinking on these affinity questions will have to be revised considerably, whenever viscosity plays a major part in pump performance.

Professor Daugherty has plotted his test results against the Reynolds number R_D and since both sets of tests were run at the same speed, this plot is identical with that against the viscosity as the only variable in R_D. It should be noted carefully that the author's curves in Figs. 14 to 16 represent data for three different speeds and therefore correlate the test material for each pump on the basis of corresponding N/ν values, with the diameter being the only constant quantity in R_D. Professor Daugherty's pump of higher efficiency for high viscosities represents the first successful attempt at a special design for viscous influences and is therefore not directly comparable to the normal pump built for highest efficiency with water.

To facilitate further comparisons with tests of other experimenters, a graphical way of determining R_D is given in Fig. 24 of this closure, with corresponding results from the author's tests integrated into three sets of correction curves for head, capacity, and power. The efficiency corrections are not shown, but can be easily obtained for any Reynolds-number value by multiplying the head and capacity corrections and dividing the product by the power-input correction factor. The use of the chart is as follows: From a known value of the impeller diameter in inches on the left scale proceed vertically upward to the intersection with the proper speed line in rpm. From here continue horizontally across to the right to the intersection with the line marked with the given viscosity in SSU (Saybolt seconds Universal). The value of R_D may now be read on the bottom scale. A vertical line extended up will locate immediately the correction factors for capacity, head, and input power.

These correction curves represent the average values from the author's tests obtained for the higher speeds which are normally employed. The individual curves are identified by the corresponding approximate specific speeds. The diagram may thus serve as a more easily applied method for practical approximations, for which Professor Moody and Mr. Tetlow have asked. The user may be reminded, however, that no claim is made as to the general validity of the correction factors, since these are based only upon the tests and the methods of analysis reported in the paper. Material from other sources may be easily compared with these findings.

Professor Moody has offered the form of an efficiency correction function which seems basically sound. The author is especially in favor of his use of $(e_w - e_0)$ therein, which represents the absolute decrease of the efficiency due to the influence of viscosity. From some preliminary graphical studies of tests on many different pumps, it seems that $(e_w - e_0)$ produces the relatively best correlation of the results, again pointing to the predominant increase of external losses especially for lower viscosities.

The author gladly complies with Professor Moody's suggestion of showing the pumps tested in sectional views by courtesy of the Ingersoll-Rand Company. Fig. 25 presents the pump labeled IL11, which indicates the closed impeller, and Fig. 26 shows the pump IL22. It is to be recalled that pump IL21 differed from the latter only by having an impeller of smaller diameter.

Little can be added to Mr. Dorer's remarks which are concerned extensively with the analysis of individual internal and external losses. The author prefers the method of determining disk friction indicated in Fig. 11 of the paper, which is based upon sound analytical and experimental evidence and would like to call attention to the considerable influence of wearing-ring friction. Mr. Dorer's Reynolds number R_N is identical with the author's R_P, as can easily be verified by substituting for $(H_v)^{1/4}$

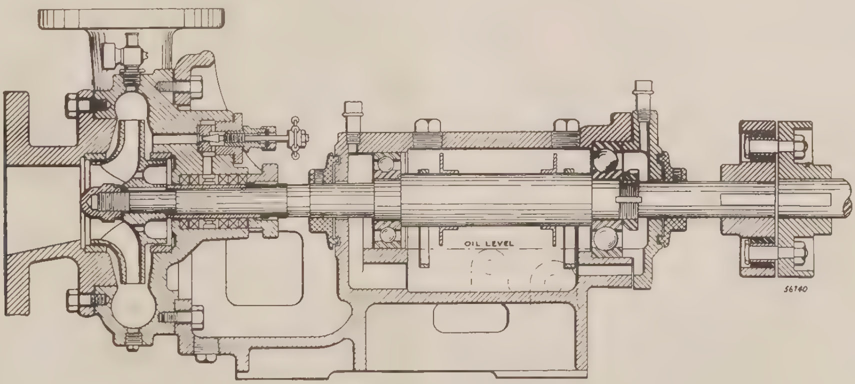

FIG. 25 CLOSED-IMPELLER-TYPE PUMP IL11

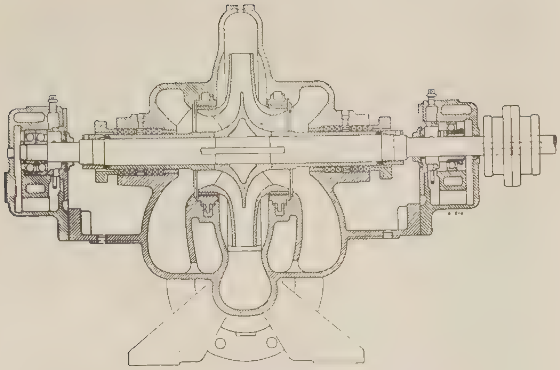

Fig. 26 Double-Suction Centrifugal Pump, IL22

in terms of $\left(\frac{Q_0}{D^2}\right)^{1/2}$ and by changing the constants corresponding to units employed. This Reynolds number differs from R_D only by the proportionality factor relating Q_o to ND^3. Since these proportionality factors are dependent upon the viscosity and Reynolds number, their use in defining a Reynolds number is impractical, because trial-and-error methods have to be employed in solving for the correction factors. Reynolds number R_D is determined by diameter, speed, and viscosity and immediately locates the proper correction. Aside from this practical advantage, R_D is of particular significance for disk and ring friction as pointed out before.

In conclusion the author wishes to express his appreciation for the interesting contributions made in the discussion. They have helped greatly to stimulate and to clarify further thought on the complexities inherent in this problem of viscous effects on centrifugal-pump performance.

APPENDIX

Auxiliary Table of Notations

Tables 1 and 2 (all dimensions in inches):

D_s = diameter of suction pipe
D_d = diameter of discharge pipe
D_1 = diameter of entrance section of impeller
D_2 = diameter of exit section of impeller
D_{sh} = diameter of shaft
B_2 = width of exit section of impeller
D_R = diameter of wearing rings
B_R = width of wearing rings
$2\,S_R$ = diametral clearance of wearing rings

Fig. 7:

$$M = \frac{a_2\sqrt{2g}}{\sqrt{1 - \frac{(d_2)^4}{(d_1)}}}$$

h = differential head of liquid, ft
Subscript (2) refers to orifice and Venturi-throat diameter; subscript (1) to diameter of line of approach. For water flowing through orifice $C_D = 0.6185$, and $K_M = 1.00$

Equations [1 to 17]:

H_w = head produced by pump for water, ft
H_0 = head produced by pump for oil, ft
Q_0' = discharge, cfs
Q_0 = discharge, gpm
d_{i_e} = equivalent eye diameter of impeller, ft
v_i = velocity in equivalent eye section, fps
d_2 = impeller diameter, ft
b_2 = impeller width, ft
ω = angular velocity in radians per sec
N = rpm of disk or impeller
u_2 = tangential velocity at impeller exit, fps
v_2 = relative velocity at impeller exit, fps
r = radius of disk or impeller
δ = thickness of boundary layer near disk
S_D = clearance between disk and housing wall
d_R = diameter of rings, ft
b_R = width of wearing rings, ft
S_R = clearance between rings
γ = specific weight of fluid, lb per cu ft
S_0 = specific gravity of oil

Fig. 10:

$\omega \cdot r$ = tangential velocity of disk
u = tangential velocity of liquid in boundary layer
v_r = radial velocity of liquid in boundary layer
$\tan \alpha_2 = \frac{v_r}{u}$
z = distance from disk surface within boundary layer ($z_{max} = \delta$)

The Theory of Moving Sources of Heat and Its Application to Metal Treatments

By D. ROSENTHAL,[1] CAMBRIDGE, MASS.

The theory of moving sources of heat has been instrumental in providing the welding engineer with a scientific criterion of weldability of steels. The author outlines briefly the fundamentals of this theory and derives appropriate solutions for linear, two- and three-dimensional flow of heat in solids of infinite size or bounded by planes. Point, linear, and plane sources of heat are examined. The solutions obtained are then applied to welding problems. It is shown that these solutions are in good agreement with the experimental results, and that they afford a close analysis of the factors governing the heat flow in welding. The most interesting result of the theory, however, is the derivation of a single formula capable of predicting the time and rate of cooling with a fairly good accuracy for a wide variety of thicknesses of steel, ranges of temperature, and welding conditions. An attempt has been made also to show how this theory could be applied to other problems of metal treatment, such as rate of extrusion in continuous casting, or control of flame-hardening and continuous quenching operations.

Introduction

THE theory of heat flow due to a moving source so far has retained little attention in the general treatment of heat flow in metals. Yet the moving source of heat plays an important part in many metallurgical processes, notably in welding. In this latter case the theory of heat flow due to a moving source has been instrumental in establishing a scientific criterion of weldability (1).[2] Similar applications of the theory are feasible in other metallurgical processes, for example, in surface-hardening or continuous casting; but the somewhat involved mathematical analysis makes it rather hard for the industrial engineer to grasp the practical implications of the theory. The purpose of this paper is to overcome this shortcoming by putting more emphasis on applications. The first part deals briefly with the mathematical aspect of the theory; the second part describes the experimental work which has been carried out in connection with the applications to welding; and the third part outlines some of the feasible applications in other metallurgical branches.

Previous Work

Apparently the theory of heat flow due to a moving source originated in connection with arc welding. Many attempts, both experimental and theoretical, had been made to describe the temperature situation created by the arc welding. Most of these early attempts have been reviewed previously (2). Because of their approximate nature, there is little point in discussing them in the present paper.

The exact theory of heat flow due to a moving point source was first applied to arc welding by the author (3) in 1935, using the experimentally established principle of a "quasi-stationary" state (4). A particular case of the general solution was treated independently by Boulton and Lance Martin (5) in 1936. More recently, Bruce (6) applied the method of instantaneous sources to another particular case of welding and, in 1941, Mahla (7) extended this method to a three-dimensional case. The solution derived by Mahla does not differ materially from that obtained previously on the assumption of the quasi-stationary state, but the method is applicable also to nonquasi-stationary states, as shown in a later section. Unfortunately, in most cases the solution becomes too unwieldy for a direct practical application.

1 Theory of Heat Flow Due to a Moving Source

The Differential Equation of the Quasi-Stationary State

Nomenclature. The following nomenclature will be used throughout the paper:

q = rate of heat, for ex., cal/sec
q' = rate of heat per unit length
q'' = rate of heat per unit section
v = speed of source
T = temperature
t = time
k = heat conductivity of metal. When expressed in C.G.S. units the dimensions of k are cal/sec cm deg C
$1/2\lambda$ = thermal diffusivity of the metal.[3] The dimensions of diffusivity are $\frac{\text{sq cm}}{\text{sec}}$ in C.G.S. units. On the other hand, if c is specific heat and ρ density, $2\lambda = \frac{c\rho}{k}$

Assumptions. Assumptions will be made as follows:

(a) The physical characteristics of the metal, i.e., k and λ are independent of the temperature.

(b) The speed v and the rate of heat input q are constant.

The Quasi-Stationary State. The differential equation of heat flow expressed in rectangular co-ordinates (x, y, z) which are referred to a fixed origin in the solid, has the well-known form

$$\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} = 2\lambda \frac{\partial T}{\partial t} \qquad [1]$$

Assume now that the heat is supplied by a point source of strength q moving with a constant speed v along the x-axis, and determine the temperature distribution around the heat source. This amounts to writing the differential Equation [1] with the point source as origin. To this end, replace in Equation [1] x by $\xi = x\text{-}vt$, where ξ is the distance of the point considered from the point source, and differentiate with respect to ξ. There follows

$$\frac{\partial^2 T}{\partial \xi^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} = -2\lambda v \frac{\partial T}{\partial \xi} + 2\lambda \frac{\partial T}{\partial t} \qquad [2]$$

Experiment shows (4) that if the solid is long enough as com-

Contributed by the Heat Transfer Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 17–20, 1946, of The American Society of Mechanical Engineers.

[3] The notation by means of a converse symbol multiplied by 2 is used here for the sake of convenience as will appear later.

pared to the extent of heat, the temperature distribution around the heat source soon becomes constant. In other words, an observer stationed at the point source fails to notice any change in the temperature around him as the source moves on. This state of heat flow is called quasi-stationary, and is defined by Equation [2] in which $\frac{\partial T}{\partial t} = 0$, i.e.

$$\frac{\partial^2 T}{\partial \xi^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} = -2\lambda v \frac{\partial T}{\partial \xi} \quad [3]$$

Equation [3] can be simplified by putting

$$T = T_0 + e^{-\lambda v \xi} \varphi(\xi, y, z) \quad [4]$$

where T_0 is the initial temperature of the solid and φ is a function to be determined. After substitution of Equation [4] in [3] and reduction of terms, the following equation is obtained

$$\frac{\partial^2 \varphi}{\partial \xi^2} + \frac{\partial^2 \varphi}{\partial y^2} + \frac{\partial^2 \varphi}{\partial z^2} - (\lambda v)^2 \varphi = 0 \quad [5]$$

or in the usual symbolic form

$$\nabla^2 \varphi - (\lambda v)^2 \varphi = 0 \quad [6]$$

Thus Equation [1] is reduced to a relatively simple form, which provides ready solutions for an infinite and semi-infinite solid, as will be shown presently.

Infinite and Semi-Infinite Solid

Linear Flow of Heat. In this case $\frac{\partial T}{\partial y} = \frac{\partial T}{\partial z} = 0$, and Equation [5] is reduced to

$$\frac{d^2 \varphi}{d \xi^2} - (\lambda v)^2 \varphi = 0 \quad [7]$$

The boundary conditions are

$$\frac{dT}{d\xi} \to 0 \quad \text{for} \quad \xi \to \pm\infty \quad [8]$$

Furthermore, considering a plane source with a rate of heat q'' per unit area

$$-\frac{dT}{d\xi} \times k \to q'' \quad \text{as} \quad \xi \to 0 \quad [9]$$

A general solution of Equation [7] can be written as follows

$$\varphi = C_1 e^{-\lambda v \xi} + C_2 e^{\lambda v \xi} \quad [10]$$

hence

$$T - T_0 = C_1 e^{-2\lambda v \xi} + C_2 \quad [11]$$

With reference to Equations [8] and [9] it is easy to see that $C_1 = 0$ when $\xi < 0$, hence for $\xi < 0$

$$T - T_0 = C_2 \quad [12]$$

Likewise $C_2 = 0$, when[4] $\xi > 0$, hence for $\xi > 0$

$$T - T_0 = C_1 e^{-2\lambda v \xi} \quad [13]$$

Also, since $T - T_0$ must have the same value for $\xi = 0$

$$C_1 = C_2$$

On the other hand, with reference to Equation [9]

$$C_1 2\lambda v k = q''$$

[4] This because $T = T_0$ for $\xi = \infty$.

or, since

$$2\lambda k = c\rho$$

$$C_1 = C_2 = q''/c\rho v \quad [14]$$

hence for $\xi < 0$

$$T - T_0 = \frac{q''}{c\rho v} \quad [15]$$

and for $\xi > 0$

$$T - T_0 = \frac{q''}{c\rho v} e^{-2\lambda v \xi} \quad [16]$$

From Equation [16] it follows that $q''/c\rho v$ is the rise of temperature at the location of the source, i.e., for $\xi = 0$, and corresponds to the maximum value of temperature reached in the solid. Equation [15] shows that once this temperature has been reached, it remains even after the source has moved further. This, of course, is the result of lack of surface losses. Calling T_1 the maximum temperature in the solid, Equations [15] and [16] become finally

for $\xi < 0$

$$T = T_1 \quad [17]$$

for $\xi > 0$

$$T = T_0 + (T_1 - T_0)e^{-2\lambda v \xi} \quad [18]$$

Heat Dissipation; Infinite Rod. If temperature gradients in the cross section of the rod are neglected, Equations [17] and [18] can be made to include heat losses through the surface. Assuming Newton's law of radiation, the rate of heat losses through unit surface area is given by the following formula

$$h(T - T_0) \quad [19]$$

Here T is the temperature of the surface and T_0 is the temperature of the surrounding medium which we shall assume to be the same as the initial temperature of the rod; h is the heat dissipation. In problems of heat flow in metals it is customary (8) to use the ratio of heat dissipation to heat conductivity

$$H = \frac{h}{k} \quad [20]$$

H will be called the dissipation ratio.

With this in mind, the differential equation of linear heat flow with surface losses has the following form (9)

$$\frac{\partial^2 T}{\partial x^2} = 2\lambda \frac{\partial T}{\partial t} + \frac{PH}{A}(T - T_0) \quad [21]$$

Here P is the perimeter and A the area of the cross section of the rod. For the case of the quasi-stationary state this equation can be reduced, as easily seen from Equation [6], to

$$\frac{d^2 \varphi}{d\xi^2} - \left[(\lambda v)^2 + \frac{PH}{A}\right]\varphi = 0 \quad [22]$$

and the solution corresponding to Equations [17] and [18] can be rewritten to read

for $\xi < 0$

$$T = T_0 + (T - T_0)e^{(\sqrt{(\lambda v)^2 + PH/A} - \lambda v)\xi} \quad [23]$$

and for $\xi > 0$

$$T = T_0 + (T - T_0)e^{-(\sqrt{(\lambda v)^2 + PH/A} + \lambda v)\xi} \quad [24]$$

The rate of heat per unit area delivered to the rod is correspondingly

for $\xi < 0$

$$q_1'' = k(T_1 - T_0)[\sqrt{(\lambda v)^2 + PH/A} - \lambda v] \ldots\ldots [25]$$

for $\xi > 0$

$$q_2'' = k(T_1 - T_0)[\sqrt{(\lambda v)^2 + PH/A} + \lambda v] \ldots\ldots [26]$$

Various applications of the foregoing equations will be found in Parts 2 and 3 of this paper.

Two-Dimensional Flow of Heat. In this case the heat flows in two directions, one of which is the x- or ξ-direction. The other direction will be taken along the y-axis, and there will be no flow in the z-direction. Thus $\partial T/\partial z = 0$, and Equation [5] becomes

$$\frac{\partial^2\varphi}{\partial\xi^2} + \frac{\partial^2\varphi}{\partial y^2} = (\lambda v)^2\varphi \ldots\ldots\ldots\ldots [27]$$

The boundary conditions are

$$\left.\begin{array}{ll} \partial T/\partial\xi \to 0 & \text{as } \xi \to \pm\infty \\ \partial T/\partial y \to 0 & \text{as } y \to \pm\infty \end{array}\right\} \ldots\ldots\ldots\ldots [28]$$

and, by considering a circle $2\pi r$ drawn around the heat source with $r = \sqrt{\xi^2 + y^2}$

$$-\frac{\partial T}{\partial r} 2\pi rk \to q' \quad \text{for } r \to 0 \ldots\ldots\ldots\ldots [29]$$

where q' is the rate of heat of a linear source.

Because of the nature of the boundary conditions and the symmetrical form of Equation [27] with respect to ξ and y, φ depends only upon the distance r from the heat source, hence Equation [27] becomes in cylindrical co-ordinates[5]

$$\frac{d^2\varphi}{dr^2} + \frac{1}{r}\frac{d\varphi}{dr} - (\lambda v)^2\varphi = 0 \ldots\ldots\ldots\ldots [30]$$

The solution of Equation [30] satisfying the boundary Condition [29] is known; it is the so-called modified Bessel function of the second kind and zero order, and is represented by the symbol $K_0(\lambda vr)$ (10).

It can be shown that this function tends to $\ln r$ as r tends to zero, hence $\frac{dK_0}{dr} \times r$ tends to a constant value. Thus $K_0(\lambda vr)$ fulfills the Condition [29]. On the other hand, this function tends to $\sqrt{\frac{\pi}{2\lambda vr}}\, e^{-\lambda vr}$ as r tends to infinity, whereby the boundary Condition [28] also is satisfied. The solution of the two-dimensional case therefore is

$$T - T_0 = \frac{q'}{2\pi k} e^{-\lambda v\xi} K_0(\lambda vr) \ldots\ldots\ldots\ldots [31]$$

This solution will be discussed in Part 2 in connection with the welding of thin plates.

Thin Plates; Surface Losses. If the thickness g of the plate is small enough to neglect the temperature gradient in the z-direction, Equation [31] can be made to include heat losses through the surface. Calling H and H' the dissipation ratios at top and bottom face of the plate, respectively, and noting that PH/A appearing in Equation [22] becomes simply $\frac{H + H'}{g}$, there follows

$$\frac{d^2\varphi}{dr^2} + \frac{1}{r}\frac{d\varphi}{dr} - \left[(\lambda v)^2 + \frac{H + H'}{g}\right]\varphi = 0 \ldots\ldots [32]$$

hence the solution

$$T - T_0 = \frac{q}{2\pi kg} e^{-\lambda v\xi} K_0\left[\sqrt{\lambda v^2 + \frac{H + H'}{g}}\, r\right] \ldots\ldots [33]$$

where q/g, which appears instead of q', is the rate of heat per unit thickness, and q is the total rate of heat of the linear source.

Linear Source of Variable Strength; No Surface Losses. In previous discussion it has been assumed that the rate of heat q' per unit thickness was a constant. If this rate varies along the thickness, an appropriate solution similar to Equation [31] can be obtained by means of cosine series. To this end develop function $q'(z)$ in Fourier series, between $z = 0$ and $z = g$. Suppose this function reads as follows

$$q'(z) = q'(0)\sum_0^n A_n \cos\frac{\pi nz}{g} \ldots\ldots\ldots\ldots [34]$$

Since $q'(z)$ is a cosine function of z, the same must be true for φ by virtue of Condition [29]. Thus the differential Equation [30] must be completed by adding the second derivative with respect to z, to read as follows

$$\frac{\partial^2\varphi}{\partial z^2} + \frac{\partial^2\varphi}{\partial r^2} + \frac{1}{r}\frac{\partial\varphi}{\partial r} - (\lambda v)^2\varphi = 0 \ldots\ldots\ldots [35]$$

It is easy to see that this equation is satisfied by a function of the form

$$\cos\frac{\pi nz}{g} K_0\left(\sqrt{\lambda v^2 + \left(\frac{\pi n}{g}\right)^2}\, r\right) \ldots\ldots\ldots [36]$$

Hence with reference to Equation [34]

$$T - T_0 = \frac{q_0'}{2\pi k} e^{-\lambda v\xi} \sum_0^n A_n \cos\frac{\pi nz}{g} K_0\left(\sqrt{\lambda v^2 + \left(\frac{\pi n}{g}\right)^2}\, r\right) \ldots\ldots [37]$$

Solution [37] has been applied to the problem of flame-cutting, and the reader is referred to a previous publication for further developments (11).

Three-Dimensional Flow. In this case the boundary conditions are

$$\left.\begin{array}{ll} \partial T/\partial\xi \to 0 & \text{for } \xi \to \pm\infty \\ \partial T/\partial y \to 0 & \text{for } y \to \pm\infty \\ \partial T/\partial z \to 0 & \text{for } z \to \pm\infty \end{array}\right\} \ldots\ldots\ldots [38]$$

and by considering a spherical surface $4\pi R^2$ drawn around the heat source with radius $R = \sqrt{\xi^2 + y^2 + z^2}$

$$-\frac{\partial T}{\partial R} 4\pi R^2 k \to q \quad \text{for } R \to 0 \ldots\ldots\ldots [39]$$

where q is the rate of heat of a point source.

Because of Conditions [38] and [39], and the symmetrical form of the differential Equation [5], φ depends only upon the distance R, hence using polar co-ordinates Equation [5] can be rewritten as follows[5]

$$\frac{d^2\varphi}{dR^2} + \frac{2}{R}\frac{d\varphi}{dR} - (\lambda v)^2\varphi = 0 \ldots\ldots\ldots\ldots [40]$$

It is easy to see that

$$\frac{d^2\varphi}{dR^2} + \frac{2}{R}\frac{d\varphi}{dR} = \frac{1}{R}\frac{d^2(R\varphi)}{dR^2}$$

hence Equation [40] becomes

$$\frac{d^2(R\varphi)}{dR^2} - (\lambda v)^2 R\varphi = 0 \ldots\ldots\ldots\ldots [41]$$

[5] Refer to (9), p. 12.

A solution of Equation [41] satisfying the boundary Conditions [38] obviously is

$$R\varphi = Ce^{-\lambda vR} \qquad [42]$$

or

$$\varphi = \frac{Ce^{-\lambda vR}}{R}$$

This solution also satisfies Conditions [39] since $\frac{d\varphi}{dR} \times R^2$ tends to a constant value as $R \rightarrow 0$. Hence the corresponding temperature distribution

$$T - T_0 = \frac{q}{4\pi k} e^{-\lambda v\xi} \frac{e^{-\lambda vR}}{R} \qquad [43]$$

This solution will be discussed in detail in connection with welding in Part 2.

Solid Bounded by Planes

The Method of Images. If the quasi-stationary state is to be preserved, the solid cannot be bounded by planes perpendicular to the direction of motion. However, the state can still remain quasi-stationary if the bounded planes are parallel to the direction of motion. This circumstance leaves out the linear flow, but retains the two- and three-dimensional flows. Assuming there is no heat loss through the bounding planes, the method of images can be used conveniently to obtain the required solutions.[6] It will be recalled that in this method fictitious sources are associated with the real source of heat in such a way that the bounding planes become planes of symmetry. Such an arrangement fulfills the condition of no radiation, and it is accomplished by locating the fictitious sources at the mirror reflections of the real source, the bounding planes acting as the corresponding plane mirrors.

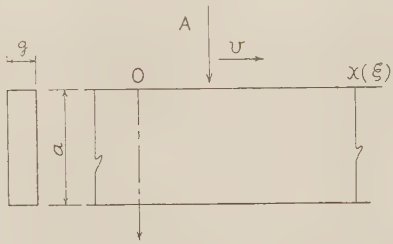

Fig. 1 Solid Bounded by Planes Paralleled to Direction of Motion

Two-Dimensional Flow. With reference to Fig. 1, the problem consists of determining the temperature distribution in a plate of width a and thickness g, heated by a linear source traveling along one of its edges. In accordance with the method of images just explained, imagine the plate extended to the size of a semi-infinite plate. Then the temperature due to the source q distributed over the thickness g would read, with reference to Equation [31]

$$T - T_0 = \frac{q}{\pi kg} e^{-\lambda v\xi} K_0(\lambda vr)$$

To this value now add the contributions of the mirror reflections of the source with respect to mirrors placed at $y = 0$ and $y = a$. These contributions are of the form

$$\frac{q}{\pi kg} e^{-\lambda v\xi} K_0(\lambda vr_n) \qquad [44]$$

[6] Reference (9) p. 158.

where

$$r_n = \sqrt{\xi^2 + (y \pm 2na)^2}$$

Hence the solution becomes

$$T - T_0 = \frac{q}{\pi kg} e^{-\lambda v\xi} \sum_{n=-\infty}^{n=+\infty} K_0(\lambda vr_n) \qquad [45]$$

From the way this solution has been built it is obvious that

$$\frac{\partial T}{\partial y} = 0 \qquad [46]$$

for $y = a$ and $y = 0$, which fulfills the boundary conditions along the two edges. Condition [29] also is fulfilled, for of all the terms $K_0(\lambda vr_n)$ which compose the solution, Equation [45], only the term $K_0(\lambda vr)$ contributes to the value of $q' = q/g$, the derivatives of the other vanishing as r when being multiplied by $2\pi r$. It remains to prove that

$$\frac{\partial T}{\partial \xi} \rightarrow 0 \quad \text{as} \quad \xi \rightarrow \pm\infty \qquad [47]$$

This can be done best by transforming Equation [45] into a Fourier series. By proceeding as explained in Appendix 2, the following expression is obtained

For $\xi > 0$

$$T - T_0 = \frac{q}{c\rho agv}\left[e^{-2\lambda v\xi} + \sum_1^\infty \frac{2}{\mu_n} e^{-(\mu_n+1)\lambda v\xi} \cos\frac{\pi ny}{a}\right] \qquad [48]$$

and for $\xi < 0$

$$T - T_0 = \frac{q}{c\rho agv}\left[1 + \sum_1^\infty \frac{2}{\mu_n} e^{(\mu_n-1)\lambda v\xi} \cos\frac{\pi ny}{a}\right] \qquad [49]$$

where

$$\mu_n = \sqrt{1 + \left(\frac{\pi n}{\lambda va}\right)^2} \qquad [50]$$

and $c\rho$ is the volume specific heat.

By differentiating Equations [48] and [49] with respect to ξ, it is seen that the derived expression tends to zero for ξ tending to both + and — infinity as required by Conditions [47].

The characteristic feature of solution, Equation [49], is that it tends to a constant temperature, which is different from the initial temperature T_0, after the source has moved away from the section considered. Calling T_2 the new temperature, there follows from Equation [49] that, if $\xi \rightarrow -\infty$

$$T_2 - T_0 = \frac{q}{c\rho agv} \qquad [51]$$

The meaning of Equation [51] is very simple. It represents a uniform rise of temperature produced by the heat q in a volume of plate covered in unit time and can be explained as follows: Because of the quasi-stationary state the temperature situation around the heat source remains unchanged, and since there are no surface losses the amount of heat delivered in unit time must be employed to raise the temperature of an additional volume of plate = agv far behind the source.

Putting Equation [51] in Equations [48] and [49], there follows

For $\xi > 0$

$$T - T_0 = (T_2 - T_0)\left[e^{-2\lambda v\xi} + \sum_1^\infty \frac{2}{\mu_n} e^{-(\mu_n+1)\lambda v\xi} \cos\frac{\pi ny}{a}\right] \qquad [52]$$

and for $\xi < 0$

$$T - T_0 = (T_2 - T_0)\left[1 + \sum_1^\infty \frac{2}{\mu_n} e^{(\mu_n - 1)\lambda v \xi} \cos\frac{\pi n y}{a}\right]. \quad [53]$$

By comparing Equations [52] and [53] with Equations [17] and [18], it is seen that the two-dimensional flow in a solid of a limited cross section tends to become linear at some distance from the source, and from Equation [50] it is apparent that this distance is so much shorter as the value of $\lambda v a$ is smaller; for example, as the plate is narrower. This trend is represented in Fig. 2 by

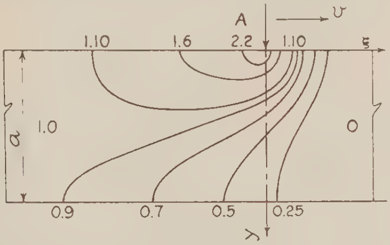

Fig. 2 Temperature Distribution in Thin and Narrow Plate Due to Heat Source Moving Along One of Its Edges
(Initial temperature taken as zero and final temperature as 1.)

means of isotherms, which for convenience have been marked in terms of the relative temperature $U = (T - T_0)/(T_2 - T_0)$. The value of $\lambda v a$ has been taken arbitrarily as 2. It is seen that in the upper half of the plate the relative temperature rises from a value $= 0$ in front of the source to a maximum which is greater than 1 in the vicinity of the source and then drops progressively down to 1 behind the source. The maximum temperature is so much more in excess of 1 as the layer under consideration is closer to the edge passed by the heat source. On the other hand, layers of metals which are close to the opposite edge never exceed 1. They approach this value asymptotically as the flow becomes more linear. This last situation is virtually reached in Fig. 2 at a distance which is smaller than twice the width of the plate.

For many practical applications, especially flame-hardening and quenching, solutions, Equations [52] and [53], have the disadvantage of becoming infinite at the location of the source. This, of course, is a direct consequence of the assumption that the heat source is reduced to a line. A more practical solution may be obtained by removing this restriction as will be shown later.

Two-Dimensional Flow; Plane Source. The inconvenience of having an infinite value of temperature at the location of the source disappears if the latter instead of being a single line is spread over a certain area, i.e., if it becomes a plane source. To demonstrate this proposition, suppose a source with a rate of heat $= q''$ per unit area covers the edge of the plate, Fig. 1, from point $\xi' = 0$ to point $\xi' = l$. This source can be represented as being composed of an infinite number of infinitely small linear sources $q''d\xi$ set side by side from $\xi' = 0$ to $\xi' = l$. If q'' is constant, then $q'' = \dfrac{q}{gl}$ where q is the rate of heat of the plane source, hence $q''d\xi' = \dfrac{qd\xi'}{lg}$. On the other hand, according to Equations [48] and [49], a linear source of strength $\dfrac{qd\xi'}{lg}$ placed at a distance ξ' from the origin contributes to the temperature of a point ξ, y in amount of

$$\frac{qd\xi'}{c\rho agvl}\left[e^{-2\lambda v(\xi - \xi')} + \sum \frac{2}{\mu_n} e^{-(\mu_n + 1)\lambda v(\xi - \xi')} \cos\frac{\pi n y}{a}\right] \quad [54]$$

for $\xi > \xi'$, and in amount of

$$\frac{qd\xi'}{c\rho agvl}\left[1 + \sum \frac{2}{\mu_n} e^{(\mu_n - 1)\lambda v(\xi - \xi')} \cos\frac{\pi n y}{a}\right] \quad [55]$$

for $\xi < \xi'$. Three cases may be distinguished, according to whether the point ξ, y is located outside or inside the portion of plate covered by the plane source.

Case 1. If $\xi > l$, Equation [54] applies to all elementary sources from $\xi' = 0$ to $\xi' = l$, and by integrating Equation [54] from $\xi' = 0$ to $\xi' = l$, there follows

$$T - T_0 = \frac{q}{c\rho agv}\left[\frac{(e^{-2\lambda vl} - 1)}{\lambda vl} e^{-2\lambda v\xi} + \sum \frac{2}{\mu_n(\mu_n + 1)} \frac{(e^{\lambda vl(\mu_n + 1)} - 1)}{\lambda vl} \times e^{-(\mu_n + 1)\lambda v\xi} \cos\frac{\pi n y}{a}\right] \quad [56]$$

Case 2. If $\xi < 0$, it is Equation [55] which applies to all elementary sources; hence by integrating Equation [55] from $\xi' = 0$ to $\xi' = l$, there follows

$$T - T_0 = \frac{q}{c\rho agv}\left[1 + \sum \frac{2}{\mu_n(\mu_n - 1)} \times \frac{1 - e^{-\lambda vl(\mu_n - 1)}}{\lambda vl} \times e^{(\mu_n - 1)\lambda v\xi} \cos\frac{\pi n y}{a}\right] \quad [57]$$

Case 3. Finally, if $l > \xi > 0$, Equation [54] applies to all elementary sources for which $0 < \xi' < \xi$, and Equation [55] applies to all sources for which $\xi < \xi' < l$. By integrating each of these expressions within the limits of its applicability, we have

$$\left.\begin{aligned} T - T_0 = \frac{q}{c\rho agv}\Bigg[&\frac{1 - e^{-2\lambda v\xi}}{\lambda vl} + \left(1 - \frac{\xi}{l}\right) \\ &+ \sum \frac{2}{\mu_n(\mu_n + 1)} \frac{1 - e^{-(\mu_n + 1)\lambda v\xi}}{\lambda vl} \cos\frac{\pi n y}{a} \\ &+ \sum \frac{2}{\mu_n(\mu_n - 1)} \frac{1 - e^{-(\mu_n - 1)\lambda v(l - \xi)}}{\lambda vl} \cos\frac{\pi n y}{a}\Bigg] \end{aligned}\right\} \quad [58]$$

It is easy to see that the maximum value of temperature occurs at $\xi = 0$, $y = 0$. For this point

$$T_1 - T_0 = \frac{q}{c\rho agv}\left[1 + \sum \frac{2}{\mu_n(\mu_n - 1)} \frac{1 - e^{-(\mu_n - 1)\lambda vl}}{\lambda vl}\right] \quad [59]$$

On the other hand, it follows from Equations [57] and [51] that for $\xi \to -\infty$, the temperature tends to the same constant value T_2 as in the case of a linear source. Therefore Equation [59] can be rewritten to read

$$T_1 - T_0 = (T_2 - T_0)\left[1 + \sum \frac{2}{\mu_n(\mu_n - 1)} \frac{1 - e^{-(\mu_n - 1)\lambda vl}}{\lambda vl}\right] \quad [60]$$

If the heat instead of being delivered is absorbed by the source, i.e., if the latter is replaced by a sink, then $T_0 > T_2 > T_1$, and Equation [60] becomes

$$T_0 - T_1 = (T_0 - T_2)\left[1 + \sum \frac{2}{\mu_n(\mu_n - 1)} \frac{1 - e^{-(\mu_n - 1)\lambda vl}}{\lambda vl}\right] \quad [61]$$

Both expressions, Equation [60] as well as [61], can find suitable applications in metal treatments, the former in flame-hardening, the latter in continuous quenching, as will be shown later in Part 3.

Remark. By comparing Equation [61] with Equation [53] it is seen that the former is represented by a series of the form

$1/n(n-1)$, while the latter is of the form $1/n$. But the series $1/n(n-1)$ is known to be absolutely convergent, whereas the series $1/n$ is divergent, if all terms are positives, and this is what happens at the location of the source, for which $\xi = 0$ and $y = 0$.

Three-Dimensional Flow. Solid bounded by planes $z = 0$ and $z = g$; no surface losses.

Following the pattern developed in the preceding section, imagine first the solid extended in the z-direction from $z = 0$ to $z = \infty$, covering one half of the space. Then the temperature due to the source of strength q located at $\xi = 0$, $y = 0$, $z = 0$ would read with reference to Equation [43]

$$T - T_0 = \frac{q}{2\pi k} e^{-\lambda v \xi} \frac{e^{-\lambda v R}}{R} \qquad [43a]$$

The factor 2 in Equation [43a], as compared to 4 in Equation [43] accounts for one half of the space.

To Equation [43a] add now the contributions of the mirror reflections of the source with respect to planes $z = 0$ and $z = g$. These contributions are of the form

$$\frac{q}{2\pi k} e^{-\lambda v \xi} \frac{e^{-\lambda v R_n}}{R_n} \qquad [62]$$

where

$$R_n = \sqrt{\xi^2 + y^2 + (z \pm 2ng)^2}$$

Hence the solution reads

$$T - T_0 = \frac{q}{2\pi k} e^{-\lambda v \xi} \sum_{-\infty}^{\infty} \frac{e^{-\lambda v R_n}}{R_n} \qquad [63]$$

From the way this solution has been built it is obvious that

$$\frac{\partial T}{\partial z} = 0 \qquad [64]$$

for $z = 0$ and $z = g$, which fulfills the condition of no radiation. Condition [39] also is fulfilled, since the derivative of all terms of Equation [63] tends to zero as R, when being multiplied by R^2, except the derivative of the term $n = 0$, which becomes a constant when being multipled by R^2.

Finally it is easy to see that

$$\left.\begin{array}{ll} \partial T/\partial \xi \rightarrow 0 & \text{as } \xi \rightarrow \pm\infty \\ \partial T/\partial y \rightarrow 0 & \text{as } y \rightarrow \pm\infty \end{array}\right\} \qquad [65]$$

which fulfills the first two Conditions [38].

By a procedure similar to that explained in Appendix 2, solution of Equation [63] can be transformed into a Fourier series to read

$$T - T_0 = \frac{q}{2\pi k g} e^{-\lambda v \xi} \left\{ K_0(\lambda v r) + 2 \sum_{1}^{\infty} K_0 \left[r \sqrt{\lambda v^2 + \left(\frac{\pi n}{g}\right)^2} \right] \cos \frac{\pi n z}{g} \right\} \qquad [66]$$

The similarity between Equations [66] and [31] is obvious. In fact, both solutions become practically identical for large values of r. This means that the solid behaves more and more like a thin plate as the distance from the heat source increases. Conversely, for values of r which are small as compared to the thickness g, Equation [63] differs little from Equation [43] which has been derived for an infinitely thick plate. This twofold aspect of solution [63] or [66] is well evidenced in the behavior of butt-welded plates, as will be demonstrated in Part 2.

Solid Bounded by a Cylinder

Because of the condition of the quasi-stationary state, the axis of the cylinder must be parallel to the direction of motion, and in most cases of practical interest it will coincide with the path of the moving source. Even so, it does not appear possible to obtain a simple solution of this problem. Recently, R. H. Cameron and the author have worked out a solution which, although far from being simple, is believed to be practically usable. However, because of the somewhat involved mathematical treatment of the solution, the presentation of their work is reserved for a separate publication.

2 APPLICATION TO ARC WELDING

Rate of Fusion of Electrode

In the process of welding, the heat generated by the arc causes the electrode to melt, thus providing the metal necessary for joining the parts to be welded. Assuming the electrode is long enough with respect to its diameter and neglecting the heat generated by the Joule effect, the process of melting for the first few inches of the electrode can be looked upon as being of a quasi-stationary nature, in so far as the temperature distribution around the welding arc is concerned. The rate of melting of the electrode is then the speed with which the arc moves along the electrode, and the temperature T at a point located at a distance ξ from the arc is equal, according to Equation [18], Part 1

$$T = T_0 + (T_1 - T_0)e^{-2\lambda v \xi} \qquad [67]$$

Here, T_0 is the initial temperature, T_1 is the temperature at the location of the arc, i.e., the temperature of fusion, 2λ is the converse of thermal diffusivity, and v is the rate of fusion.

Equation [67] assumes that there are no surface losses, in other words, that the electrode is perfectly insulated. This assumption is an approximation but it offsets to a great extent the error introduced by neglecting the Joule effect in the electrode. That this is so is proved by the fact that the relation between the rate of fusion v and current density i, derived from the foregoing assumptions, is in good agreement with the experiment. This relation is obtained as follows:

It has been shown in Part 1 that in the absence of surface losses the rate of heat q'' absorbed in the electrode per unit area is

$$q'' = (T_1 - T_0)c\rho v \qquad [68]$$

$c\rho$ is the specific volume heat content (c specific heat, ρ density), and T_1, T_0, and v, as previously, the temperature of fusion, the initial temperature, and the rate of fusion, respectively. On the other hand, q'' is a fraction of the heat generated by the arc, which is proportional to the product VI, where V is the voltage drop across the arc, and I is the current intensity. Experiment shows that for a given type of electrode the voltage drop V is fairly constant within a large range of current densities, and that for various types of coated-steel electrodes it varies between 25 and 35 volts. Thus for a given type of electrode of a diameter d, it is possible to write

$$q'' \frac{\pi d^2}{4} = fI \qquad [69]$$

where f is a constant (13).

Substituting in Equation [68], there follows

$$\frac{fI}{\pi d^2/4} = (T_1 - T_0)c\rho v$$

hence

$$v = f_0 i \qquad [70]$$

where

$$f_0 = \frac{f}{(T_1 - T_0)c\rho}$$

Relation, Equation [70] has been checked experimentally and has been found to hold within a reasonable degree of accuracy for moderate current densities and for the first 3 to 4 in. of the electrode. The values of f_0 reported in the literature for a mild-steel electrode lie between 1.24×10^{-3} and 1.56×10^{-3} cu in. per amp per min.

Substituting Equation [70] in [67] there follows

$$T = T_0 + (T_1 - T_0)e^{-2\lambda f_0 i \xi}$$

or putting

$$i = I \Big/ \frac{\pi d^2}{4}$$

$$T = T_0 + (T_i - T_0)e^{-f' I \xi} \qquad [71]$$

where

$$f' = \frac{2\lambda f_0}{\pi d^2/4} = \frac{8\lambda f_0}{\pi d^2} \qquad [72]$$

In Fig. 3 the ratios of $(T - T_0)/(T_1 - T_0)$ have been plotted against the distance ξ from the location of the arc in inches, for four different values of current density, namely, 145, 165, 185, and 240 amp. These values may be considered as being within workable range of current intensities for a $^5/_{32}$-in. mild-steel electrode. The following values were used to calculate the factor f' appearing in Equation [71]

$$2\lambda = 1.00 \text{ sq in. per min}$$

$$f_0 = 1.25 \times 10^{-3} \text{ cu in. per amp per min}$$

$$d = {}^5/_{32} \text{ in.}$$

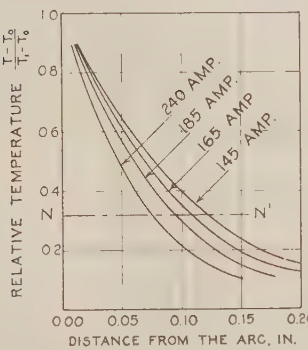

Fig. 3 Temperature Distribution in Mild-Steel Electrode for Various Current Intensities

It appears from Fig. 3 that the higher the current intensity the shorter is the range over which the electrode is affected by the heat of the arc. This condition is well illustrated in Fig. 4, which shows macroetched sections made through the axis of a $^5/_{32}$-in. electrode submitted to the current intensities mentioned. Because of the recrystallization process the part of the electrode which has been heated beyond some 950 F responds more readily to the etching (10 per cent solution of nitric acid) than the rest of the electrode. It is seen that in accordance with diagrams, Fig. 3, the extent of the recrystallized zone is greater for the low current intensity than it is for high current intensity, see also line NN', Fig. 3, corresponding to the temperature of recrystallization of mild steel ($T_1 - T_0/T_1 - T_0 \approx 0.32$).

Arc-Welding of Thin Plates

Temperature Distribution in an Edge-Welded Plate. The validity of Equation [31], Part 1, in the case of arc welding was tested experimentally by Schmerber and the author (12). They deposited a weld layer at a constant rate along one of the edges of a flat bar, 5.5 in. wide, and measured the variation of temperature in the bar produced by this operation. Assuming no losses of heat through the surface, the temperature can be taken as being uniform through the thickness. Hence the heat flow is of a two-dimensional nature, and Equation [31], Part 1, is applicable. For the purpose of computation, a constant value of heat conductivity k was adopted = 0.1 cal per deg C per cm per sec, but the diffusivity coefficient $1/2\lambda$ was made to vary according to a linear law with the temperature. Under these circumstances, the agreement between the measurement and computation was quite satisfactory, except at the immediate neighborhood of the arc, Fig. 5. There, the computed isotherms were closer to the origin than the measured values. This discrepancy could be explained by the fact that the theory considered the source of heat as a line, whereas in practice the source of heat had a finite size.

Rate of Cooling in Thin Butt-Welded Plates. On the basis of the foregoing experiment it can be expected that Equation [31] will be applicable also to the case of thin butt-welded plates. Hess and his co-workers (14) determined experimentally the rates of cooling produced very near to the weld in plates of various thicknesses. If the temperature is assumed constant through the thickness, these rates of cooling can also be derived from Equation [31] by differentiating the latter with respect to time. In so doing, attention is called to the fact that in the present application the rates of cooling are measured at some distance from the location of the heat source. Hence, according to the theory of Bessel functions (10), Equation [31] can be reduced to a more simple expression to read

$$T - T_0 = \frac{q}{2\pi k g}\sqrt{\frac{\pi}{2\lambda v r}}\, e^{-\lambda v \xi - \lambda v r}$$

$$= \frac{q}{2\pi k g}\,\frac{e^{-\lambda v(\xi + r)}}{\sqrt{vr}}\sqrt{\frac{\pi}{2\lambda}} \qquad [73]$$

where T is the temperature measured at a distance $r = \sqrt{\xi^2 + y^2}$ from the source, T_0 the initial temperature, q the rate of heat input, v the speed of the source, and k, $c\rho$, and $1/2\lambda = k/c\rho$ as

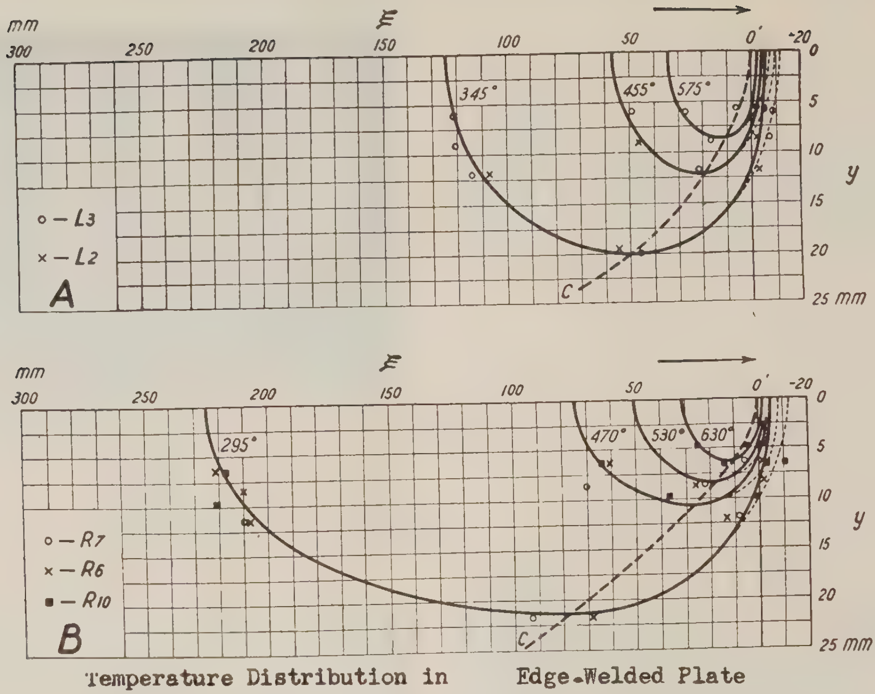

Fig. 5 Temperature Distribution in Edge-Welded Plate

(Continuous lines, calculated; broken lines, experimental. A, Current, 93 amp; welding speed, 0.21 cm per sec or 4.95 ipm. B, Current, 141 amp; welding speed, 0.43 cm per sec or 10.1 ipm. L2, L3, R7, R6, R10 are different specimens. Courtesy *The Welding Journal*.)

previously, the heat conductivity, volume specific heat, and heat diffusivity, respectively.

Along the weld, $y = 0$, hence $r = /\xi/$; also $\xi = -vt$, hence Equation [73] can be further simplified as follows

$$T - T_0 = \frac{1}{2\sqrt{\pi k c\rho}} \times \frac{q}{gv} \times \frac{1}{\sqrt{t}} \quad [74]$$

Expression q/gv represents, as it is easy to see, the amount of heat per unit section of plate, measured in the direction of welding. In practice, the welding conditions are defined by another value more readily determined, namely, the total amount of energy J/gv per unit section of plate supplied by the arc, expressed in joules per sq in. This value is related to the former by a coefficient which defines the heat efficiency of the arc, and which Hess and co-workers represented by the symbol (I.F.) input factor. Thus

$$T - T_0 = \frac{(\text{I.F.})}{2\sqrt{kc\rho\pi}} \times \frac{J}{gv} \times \frac{1}{\sqrt{t}} \quad [75]$$

or

$$(T - T_0)\sqrt{t} = C \text{ (independent of time)} \quad [76]$$

By differentiating with respect to time there follows

$$\frac{dT}{dt}\sqrt{t} + \frac{1}{2}\,\frac{T - T_0}{\sqrt{t}} = 0$$

or

$$\frac{dT}{dt} = -\frac{1}{2}\,\frac{T - T_0}{t} \quad [77]$$

Equation [77], due to Hess and co-workers (14), states that the rate of cooling at a given temperature T is proportional not only to this temperature but also to the converse of time t that it has taken for the point considered to cool down to the temperature T after the welding arc has passed through this point. In this respect the rate of cooling in welding is quite different from the rate of cooling in quenching, for which no dependence on time is assumed (15). As will appear later, the factor 1/2 at the right-hand side of Equation [77] is characteristic for the two-dimensional problem of welding.

If time t is eliminated from Equations [77] and [75], the following expression is obtained

$$\frac{dT}{dt} = -\frac{2\pi k c\rho}{(\text{I.F.})^2} \times \left(\frac{gv}{J}\right)^2 \times (T - T_0)^3 \quad [78]$$

or

$$\left(\frac{dT}{dt}\right)^{1/2} \times \frac{J}{vg} = \frac{\sqrt{2\pi k c\rho}}{(\text{I.F.})} \times (T - T_0)^{3/2} \quad [79]$$

Since the right-hand side of Equation [79] is a constant for a given type of steel, electrode, and temperature T, the product on the left-hand side also must be constant, no matter what are the individual values of rates of cooling, energy inputs, and thickness. This condition has been tested for the case of $^1/_4$-in. and $^1/_2$-in. butt-welded plates using experimental results of Hess and co-workers (14), obtained very near to the weld.[7] When the products figuring on the left-hand side of Equation [79] are plotted as a function of rates of cooling at 1300 F, the diagram, Fig. 6, is obtained. From this diagram it appears that the $^1/_4$-in. butt-welded plate behaves like a thin plate for all rates of cooling at 1300 F, while the $^1/_2$-in. plate behaves like a thin plate only for rates of

[7] It can be shown that the rate of cooling very near to the weld is not appreciably different from that in the weld itself.

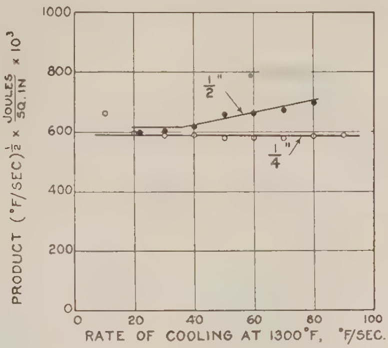

FIG. 6 TWO-DIMENSIONAL HEAT FLOW IN $1/4$- AND $1/2$-IN. BUTT-WELDED PLATES AS EVIDENCED BY CONSTANT VALUE OF PRODUCT INDICATED

cooling at 1300 F which are smaller than 50 deg F per sec. The reason for this discrepancy will be discussed later.

ARC WELDING OF THICK PLATES

Rate of Cooling in Butt-Welded Plates. Following the ideas developed in the section on the arc welding of thin plates, it may be anticipated that since Equation [31] has approximated fairly well the conditions of heat flow in butt-welded plates, Equation [43] may approximate likewise the conditions of heat flow in thick butt-welded plates. If the observation is limited to the surface of the weld, the distance R, figuring in Equation [43], is simply the distance $/\xi/$ covered by the arc in a given period of time t; thus

$$T - T_0 = \frac{q}{2\pi k} \times \frac{1}{\xi} \qquad [80]$$

Equation [80] does not contain explicitly the speed v, and it does not depend upon the diffusivity of the material. In fact the same expression is obtained, if the point source instead of being in motion remains stationary, except that in this case ξ represents not only the distance behind the source, but the distance from the source measured in any direction.[8] On the other hand, if ξ is expressed in terms of the distance covered by the arc in time t, then $\xi = vt$, and Equation [80] becomes

$$T - T_0 = \frac{1}{2\pi k} \times \frac{q}{v} \times \frac{1}{t} \qquad [81]$$

The quantity (q/v) represents the heat input per unit length and is to be compared with a similar quantity (q/vg) used in the study of thin plates. As in the latter case, we shall write

$$q/v = (\text{I.F.})J/v \qquad [82]$$

where J/v represents the total energy input of the arc per unit length and (I.F.) the heat efficiency of the arc. With reference to Equation [82], Equation [81] may be rewritten as follows

$$(T - T_0) \times t = C \text{ (independent of time)} \qquad [83]$$

Hence by differentiating

$$\frac{dT}{dt} = -\frac{T - T_0}{t} \qquad [84]$$

This expression, also due to Hess and co-workers (14), differs from Equation [77], derived previously for the rate of cooling in a thin plate, only by the absence of the factor 1/2. Thus if conditions of welding are such that the same temperature T is reached at the same time t in both the thin and thick plates, the rate of cooling still will be twice as great in the thick plate as in the thin one.

If time t is eliminated from Equations [84] and [81], then with reference to Equation [82] the following formula is obtained

$$\frac{dT}{dt} = -\frac{2\pi k}{(\text{I.F.})} \times \frac{v}{J} \times (T - T_0)^2 \qquad [85]$$

or

$$\frac{dT}{dt} \times \frac{J}{v} = -\frac{2\pi k}{(\text{I.F.})} \times (T - T_0)^2 \qquad [86]$$

The right-hand side of Equation [86] is a constant for a given temperature and a given material, hence the product on the left-hand side also must be constant for any particular value of rate of cooling, energy input, and speed.

Although, strictly speaking, this condition holds only for the points of weld deposit for which $R = \xi$, points of the base metal very close to the weld may be expected to satisfy the condition mentioned with a reasonable degree of accuracy. With this in mind, experimental results of Hess and co-workers (14) on 1 and $1^1/_2$-in. steel plates have been used to compute the products figuring on the left-hand side of Equation [86] for various rates of cooling at 1300 F. When plotted as a function of these rates, they gave a fairly constant value, Fig. 7. The values for the $1^1/_2$-in. plate are in general more consistent than those for the 1-in. plate. Thus the $1^1/_2$-in. plate and to some extent also the 1-in. plate behave under the particular condition of cooling like plates of infinite thickness.

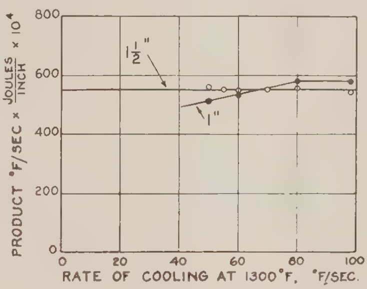

FIG. 7 THREE-DIMENSIONAL HEAT FLOW IN 1- AND $1^1/_2$-IN. BUTT-WELDED PLATES AS EVIDENCED BY CONSTANT VALUE OF PRODUCT INDICATED

Determination of Heat Diffusivity From Rates of Cooling in Thin and Thick Butt-Welded Plates. If rates of cooling have been determined for a particular temperature T and known conditions of welding in a thin and thick butt-welded plate, then assuming the same heat efficiency (I.F.) in both cases, there follows when Equation [75] is divided by Equation [85]

$$\frac{\left[\left(\frac{dT}{dt}\right)^{1/2}\left(\frac{J}{vg}\right)\right]}{\left[\frac{dT}{dt} \times \frac{J}{v}\right]} = \sqrt{\frac{c\rho}{2k}} \times \frac{1}{\sqrt{\pi}} (T - T_0)^{-1/2} \qquad [87]$$

but

$$\frac{c\rho}{2k} = \lambda$$

hence the diffusivity

$$\frac{1}{2\lambda} = \frac{1}{2\pi(T - T_0)} \times \frac{\left[\frac{dT}{dt} \times \frac{J}{v}\right]^2 \text{ thick plate}}{\left[\left(\frac{dT}{dt}\right)^{1/2} \times \frac{J}{vg}\right]^2 \text{ thin plate}} \qquad [88]$$

[8] Reference (9) p. 151.

Substituting in Equation [88] the values taken from Figs. 6 and 7, for the $^1/_4$-in. and $1^1/_2$-in. plates, respectively, the value of the diffusivity becomes

$$\frac{1}{2\lambda} = \frac{1}{2\pi(1300 - 68)} \times \frac{(550 \times 10^4)^2}{(590 \times 10^3)^2} = 0.0112 \frac{\text{in.}^2}{\text{sec}}$$

$$= 0.072 \frac{\text{cm}^2}{\text{sec}}$$

as against the value of 0.0685, computed for pure iron from the data of the International Tables for 1300 F (16).

Considering the uncertainty attached to the determination of the heat conductivity k, and the probable error of measurements, this agreement appears quite satisfactory. However, it must be borne in mind that the assumption on which Equation [88] is based precludes any variation of the diffusivity with temperature, hence the value of 0.072 sq cm per sec must be regarded as an average rather than as a particular value of the diffusivity.

Temperature Distribution in Thick (and Thin) Arc-Welded Plates. On the basis of the foregoing results it can be assumed that the application of Equation [43] will yield a satisfactory picture of the temperature distribution during welding in thick butt-welded plates. More specifically, the conception will apply to a situation created by a top weld layer when the plates have been allowed to cool down to the room temperature. This situation is represented in Fig. 8 for various conditions of welding by means of a family of isotherms drawn around the instantaneous position of the electrode (11). Because of the quasi-stationary state of heat flow, the same figure may be used to depict the variation of temperature at a given section of plate and at various instances of welding.

For the purpose of computation, the following values were substituted in Equation [43], using C.G.S. units

q = 0.239 (I.F.) $\times V \times I$ where 0.239 is the thermal equivalent of watts
(I.F.) = heat efficiency of arc assumed = 0.65 (12)
V = voltage drop in arc assumed = 25 volts (12)
I = current intensity in amp, variable
k = heat conductivity—0.1 cal per cm per deg C per sec, for steel and 0.485 cal per cm per deg C per sec for aluminum
λ = one half of the converse value of diffusivity, assumed = 5 sec per sq cm for steel and 1.2 sec per sq cm for aluminum

The main characteristics of the temperature distribution obtained under these conditions, Fig. 8, are as follows:

1 The rise of temperature in front of the heat source is much steeper than the fall of temperature behind the heat source.

2 Because of the fact that the heat does not propagate instantly in metals, the temperature does not pass through the maximum at the same time at various points of the same cross section. There is a lag at points which are farther away from the weld, as shown by curve n-n connecting the points of maximum temperature. This lag is a function of the speed of welding and diffusivity of metal (compare Fig. 8, A, B, and D).

3 Considering an instantaneous position of the electrode, curve n-n separates points in the solid with rising temperature from points in the solid with falling temperature.

As for the influence of the welding conditions, it is seen that:

1 An increase in the speed of welding, Fig. 8, A and B, produces a greater lag in the temperature distribution at a given cross section, hence the heat is more concentrated around the heat source. However, the temperature distribution along the line of welding, behind the electrode, remains unchanged, in accordance with Equation [80].

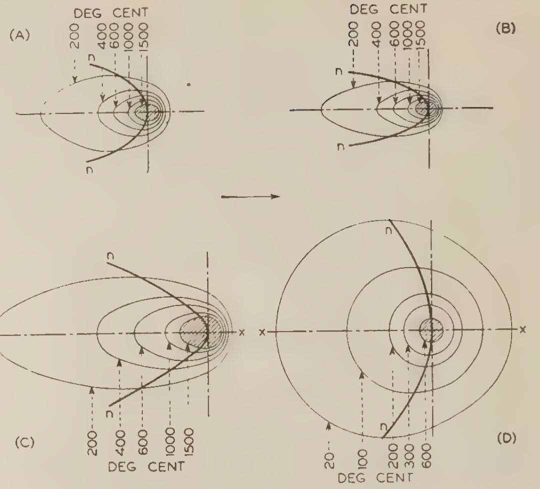

Fig. 8 Temperature Distribution in Thick Butt-Welded Plate
(For details see the text. Courtesy of *The Welding Journal.*)

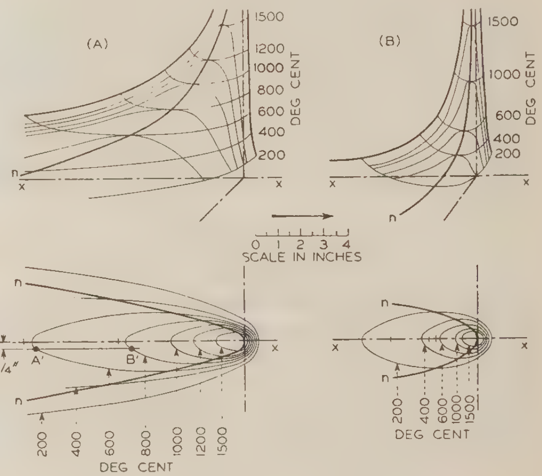

Fig. 9 Temperature Distribution in Thin and Thick Butt-Welded Plate
(*Left*, thin plate, 0.2 in. thick; *right*, thick plate. Same material, i. e., mild steel, and same welding technique in both cases, i.e., 200 amp, 8.3 ipm. Top view isometric projection; bottom view topographic projection. Courtesy of *The Welding Journal.*)

2 An increase in the current intensity, Fig. 8, A and C, extends the range of heat in the solid, but does not affect the shape of isotherms.

3 An increase in the heat conductivity and diffusivity of metal, Fig. 8, C and D, affects both the shape and the size of isotherms. The increase of the range of heating in front of the electrode is especially noteworthy.

4 An increase in the initial temperature, i.e., the preheating, causes a corresponding increase in the numerical value of each isotherm, but does not change its shape or size. However, the preheating has a marked effect upon the rate of cooling, as shown by Equation [85]. This effect is discussed in more detail in the experimental work on weldability (14) and (17).

Basically the same conclusions apply to thin welded plates, as can be easily demonstrated by means of Equation [73]. However, there is a fundamental difference in the conditions of welding of a thin and thick plate, due to the different nature of heat

flow. This difference is well apparent in the shape and size of isotherms drawn in Fig. 9.

Application to Actual Welding Practice

Determination of Cooling Time. In so far as welding practice is concerned, neither of the solutions already discussed is quite satisfactory. Because of the finite thickness of plates, the conditions of welding seldom correspond to that of a very thin or very thick plate. At a short distance from the arc there is a considerable temperature gradient through the thickness, but as the arc moves away from the section considered, the temperature becomes more uniform across the thickness. Thus the heat flow changes from a three-dimensional state to a two-dimensional one, as the distance from the arc increases. This condition has been discussed in Part 1, and an appropriate solution for this case has been obtained in the form of Equation [63].

In actual welding practice it is important to determine the time required for the weld to cool down to a given temperature, rather than to obtain a complete pattern of the temperature distribution around the electrode. Under these circumstances Equation [63] can be simplified by writing for a given spot of the weld bead, t seconds after it has been deposited on a plate of thickness, g

$$\xi = -vt;\ y = 0;\ z = 0$$

$$R_0 = |vt|;\ R_n = \sqrt{(vt)^2 + (2ng)^2},\ n = 1, 2, 3 \ldots \quad [89]$$

Substituting in Equation [63], there follows

$$T - T_0 = \frac{1}{2\pi k} \times \frac{q}{v} \times \frac{\mu}{t} \quad [90]$$

where

$$\mu = 1 + 2\sum \frac{e^{-\lambda v^2 t(s_n - 1)}}{s_n} \quad [91]$$

and

$$s_n = R_n/vt$$

As previously, the rate of heat delivered to the plate will be replaced by the rate of energy input of the welding arc, J multiplied by the heat efficiency of the arc (I.F.), thus

$$T - T_0 = \frac{(\text{I.F.})}{2\pi k} \times \frac{J}{v} \times \frac{\mu}{t} \quad [92]$$

Equation [92] can be made to correspond "formally" to Equation [81] derived for a very thick plate, by introducing a "fictitious" time of cooling $t^* = t/\mu$, which for convenience we shall call the "reduced" time of cooling. With this in mind Equation [92] can be rewritten as follows

$$T - T_0 = \frac{(\text{I.F.})}{2\pi k} \times \frac{J}{v} \times \frac{1}{t^*} \quad [93]$$

As seen from Equation [91], the reduced time of cooling depends upon the thickness of the plate g, on the speed of welding v, and the diffusivity of metal $1/2\lambda$. Actually, however, the thickness is the major factor, and for the usual range of welding speeds, from 6 to 12 ipm, the influence of speed can be neglected.

Fig. 10 shows the relation between the true and reduced time of cooling for various thicknesses of steel, assuming a diffusivity of 1 sq in. per min and a welding speed of 7 ipm. It is seen that as the time of cooling increases, the value of the reduced time of cooling, t^* differs more and more from that of the true time of cooling t, and so more so as the thickness is smaller. Since Equation [93] formally represents the conditions of a very thick plate and of a three-dimensional state of heat flow, the discrepancy between t and t^* is a measure of the departure from a three-dimensional heat flow. On the basis of Fig. 10 it may be predicted that in the vast majority of cases the $1/4$-in. plate will behave like a very thin plate, and the $1\,1/2$-in. plate like a very thick plate, and this prediction is in accordance with the findings of this and the preceding section. Also, it may be safely stated that plates over $1\,1/2$ in. thick will always behave like a very thick plate. Thus for plates thicker than $1\,1/2$ in. the reduced and the true cooling times are the same.

How well Equation [93] fits the actual conditions of welding is best determined by comparing the time of cooling computed from this formula using the chart, Fig. 10, with the time of cooling

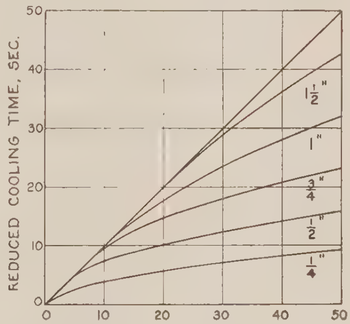

Fig. 10 Relation Between Cooling Time and Reduced Cooling Time for Plates of Various Thickness

measured in the experimental work of Hess and co-workers (14) on steel plates. In doing so, it must be remembered that the actual measurements of temperature were made not in the weld bead itself, but at a small distance from the bead. However, it can be shown that the error due to this factor is small after the first 5 to 10 sec of cooling. Another important factor is the proper choice of the heat efficiency (I.F.), and the heat conductivity k. From previous work (12), the I.F. was assumed to be 0.65. As for the heat conductivity k, a few trials showed that the value of $k = 0.080$ cal per deg C per sec fits best the experimental results at 1300 F. This value is commensurate with that determined previously, Equation [88].

Using the values given and expressing the temperature T in deg F, the energy input J/v in joules per in., and the reduced time t^* in seconds, Equation [93] reads for the case of butt-welded steel plates as follows

$$T - T_0 = 0.22\left(\frac{J}{v}\right)\frac{1}{t^*}$$

hence the reduced time of cooling

$$t^* = \frac{0.22}{T - T_0}\frac{J}{v} \quad [94]$$

Figs. 11 to 15, inclusive, show the agreement between computed and measured times of cooling for various thicknesses using three or four different energy inputs. The agreement in the important range of temperatures from 1300 to 575 F, is in general better than 5 per cent if no preheat is employed. The agreement is not as good with preheated plates, probably because the preheating operation was not maintained during welding (14). Notwithstanding this discrepancy, the general validity of Equation [93] in the range of temperatures from 1300 to 575 F may be considered as sufficiently established for practical purposes.

Determination of Rates of Cooling. By differentiating Equation [92] with respect to time there follows that (18)

$$\frac{dT}{dt} = -\frac{(\mathrm{I.F.})}{2\pi k}\frac{J}{v}\frac{\mu'}{t^2} \dots\dots\dots\dots\dots [95]$$

where

$$\mu' = 1 - 2\sum \frac{e^{-\lambda v^2 t(s_n - 1)}}{s_n^{\,2}}\,[\lambda v^2 t(s_n - 1)s_n - 1] \dots [96]$$

(Continuous lines computed; isolated circles measured by Hess and coworkers. 1, 42,400 joules per in.; 2, 52,700 joules per in.; 3, 67,000 joules per in.)

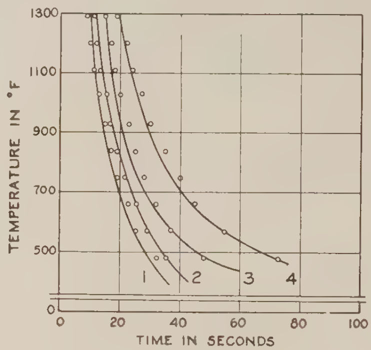

Fig. 15 Weld-Cooling Curves in 1 1/2-In. Plates at Room Temperature

(Continuous lines computed; isolated circles measured by Hess and coworkers. 1, 53,000 joules per in.; 2, 63,500 joules per in.; 3, 76,400 joules per in.; 4, 100,500 joules per in.)

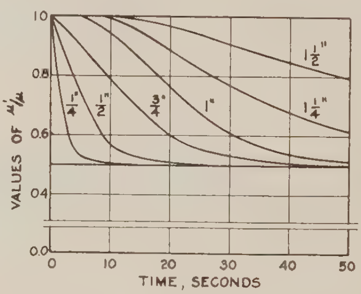

Fig. 16 Relation Between Weld-Cooling Time t and Coefficient $\left(\frac{\mu'}{\mu}\right)$ for Various Thicknesses of Steel

hence by comparing Equation [96] with Equation [92]

$$\frac{dT}{dt} = -\frac{T - T_0}{t}\frac{\mu'}{\mu} \dots\dots\dots\dots\dots [97]$$

Equation [97] is of the same type as Equations [77] and [84] for the thin and thick plates, respectively; the only difference is that the coefficient (μ'/μ) instead of being a constant is a function of time and thickness, and to a much lesser degree of speed of welding and diffusivity. Assuming as previously, the value of 1 sq in. per min for the diffusivity and 7 ipm for the speed of welding, Fig. 16 shows the dependence of (μ'/μ) on time for various

thicknesses of plate. As expected, the values of (μ'/μ) vary between $^1/_2$ and 1, the line $^1/_2$ denoting conditions identical to that of a very thin plate and the value 1, conditions identical to that of a very thick plate. In accordance with previous results it is seen that the $^1/_4$-in. plate behaves like a thin plate less than 5 sec after the cooling process has started, whereas the $1^1/_2$-in. plate remains practically under the conditions of a very thick plate up to 30 sec of cooling.

Equations [93] and [97] along with charts, Figs. 10 and 16, may be used conveniently for a speedy determination of rates of cooling.

Suppose, for example, it is desired to determine the rates of cooling in a $^3/_4$-in. plate when using an energy input of 50,000 joules per in. The three following temperatures of preheat will be examined: 72 deg, 200 deg, and 400 deg F.

From Equation [93] the corresponding reduced times of cooling are 11.8, 13.7, and 18.4 sec.

Referring to the chart, Fig. 10, we find for a $^3/_4$-in. plate the true cooling times, namely, 13.5, 18.0, and 30.5 sec, respectively, and from the chart, Fig. 16, the corresponding values of $(\mu'/\mu) =$ 0.72, 0.64, and 0.54, respectively.

Substituting in Equation [97], the following rates of cooling are obtained: 49.5 deg F per sec, 27.2 deg F per sec, and 10.5 deg F per sec, as compared to the values determined by Hess and coworkers, namely, 51 deg F per sec, 32 deg F per sec, and 15 deg F per sec. As expected, the computed rates of cooling are lower than those actually measured for higher temperatures of preheat.

3 MISCELLANEOUS APPLICATIONS OF THEORY OF MOVING SOURCES

Introduction

Because of lack of experimental data, the applications described in this part are of a more or less tentative character. The purpose of this discussion is not so much to arrive at numerical results as it is to find a scientific approach to the solution of the problems presented. In view of the success which such an approach has had in the problems of welding, it is believed that the considerations which follow will be of more than academic interest.

Rate of Extrusion in Continuous Casting. Continuous casting is a metallurgical process in which liquid metal is fed into a die and extruded in the form of a solid rod at a constant rate by means of a pair of rollers placed behind the die (19). To make the extrusion operation possible the rod must leave the die at a temperature at which the metal can be hot-worked and which consequently represents a given fraction of the temperature of fusion. In other words, the die must be capable of removing the heat from the cast metal to bring about the required drop of temperature. If radial temperature gradients in the rod are neglected, this drop of temperature may be regarded as being produced by a linear flow of heat with surface losses. On the other hand, by the process of extrusion each section of the rod is moved gradually from the inlet of the die where it is at the temperature of fusion T_1 to the outlet of the die, where it has been cooled down to the temperature of extrusion T_2. Thus the heat flow is of a quasi-stationary nature and Equation [23] is applicable. If the die is kept at a constant temperature T_0 and if the length of the die from the inlet to the outlet is L, then Equation [23] may be rewritten as follows

$$T_2 - T_0 = (T_1 - T_0)e^{-(\sqrt{\lambda^2v^2+PH/A} - \lambda v)L} \quad \ldots\ldots [98]$$

The remaining symbols in Equation [98] have the following meaning

λ = one half of the converse value of diffusivity
v = rate of extrusion
P = perimeter of rod
A = cross section of rod
H = dissipation ratio, see Equation [20]

For a circular rod of diameter D, the fraction $P/A = 4/D$. Putting further

$$\ln \frac{T_2 - T_0}{T_1 - T_0} = -m \quad \ldots\ldots [99]$$

Equation [98] becomes

$$m = \left[\sqrt{(\lambda v)^2 + \frac{4H}{D}} - \lambda v\right] L \quad \ldots\ldots [100]$$

or

$$m^2 = 2m\lambda vL + \frac{4HL^2}{D}$$

or

$$2\lambda vD = \frac{4HD}{m} \times \frac{L}{D} - m\Big/\frac{L}{D} \quad \ldots\ldots [101]$$

Assuming a constant value of m, Equation [101] gives the relation between the rate of extrusion v and the mechanical and thermal characteristics of the extrusion. The former is represented by the ratio L/D which is a function of the friction between the die and the cast.

Since the load-carrying capacity of the rod at the outlet of the die has a limiting value, the higher the friction coefficient, the smaller the ratio L/D. On the other hand, the thermal characteristics of the extrusion process are determined (*a*) by the coefficient 2λ, which is the ratio of the volume heat capacity of the rod to its heat conductivity k, i.e., $\frac{c\rho}{k}$ (c = specific heat and ρ = density); and (*b*) by the coefficient H, which is the ratio of the heat dissipation h, and the heat conductivity of the rod, k. Thus both 2λ and H contain k in the denominator. This fact will be brought out later in the discussion.

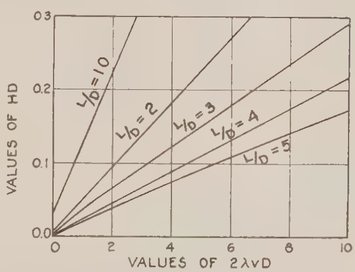

Fig. 17 Relation Between Rate of Extrusion and Heat-Dissipation Ratio in Continuous Casting

Fig. 17 shows the relation between the rate of extrusion and the surface transfer coefficient of the interface between the die and the rod for various values of L/D, computed according to Equation [101]. For the purpose of computation, the fraction $T_2 - T_0/T_1 - T_0$ has been taken as 0.7; thus ln 0.7 = —0.36. Likewise, dimensionless numbers rather than specific values of speed and dissipation ratio have been plotted in order to make the discussion more general. Because of the fact that for values of $L/D > 2$ the second term on the right-hand side of Equation [101] becomes very small as compared to the first one, the speed of extrusion increases almost proportionally to the coefficient H and the relative length of the die L/D. It also increases with the ratio $H/2\lambda$, which as pointed out previously, is nothing else but the ratio of the heat dissipation h to the volume heat capacity

of the metal. The fact that the heat conductivity of the cast metal does not appear in these relations is noteworthy. It shows, for example, that other conditions being equal, the rate of extrusion of copper wire will not be substantially greater than that of iron wire, in spite of the much higher heat conductivity, as the volume heat capacity is not very much different for these metals.

To obtain an approximate idea of the order of magnitude of the rate of extrusion which can be expected, assume the following values for an iron wire 1 cm diam ($\sim$ 3/8-in.) when cast in a metallic die

h = 0.012 cal per sq cm per deg C per sec (20)
k = 0.08 cal per cm per deg C per sec (16)
$c\rho$ = 1.2 cal per cu cm (16)[9]

hence

$$HD = 0.15 \text{ and } 2\lambda D = 15 \text{ sec per cm}$$

Assuming further L/D = 2, 3, and 4, respectively, the following values of $2\lambda vD$ are obtained from Fig. 17: 3.15, 4.8, and 6.6, hence

$$v = 0.2 \text{ cm per sec, } 0.33 \text{ cm per sec, and } 0.44 \text{ cm per sec}$$

Actually, these values may be substantially increased by improving both the heat dissipation h and the lubrication condition between the mold and cast, i.e., the ratio L/D, when using graphite instead of metal for the dies (19). At present, none of these coefficients is very accurately known to permit more than a qualitative statement. However, a method of obtaining a value of some of these coefficients is proposed in the following section.

Method of Determining Value of Diffusivity and Heat-Dissipation Ratio. Equations [23] and [24] provide a convenient method of obtaining, in a single experiment, the coefficients λ and H, the former being one half of the converse value of diffusivity, the latter the dissipation ratio. To this end the metal to be tested is formed into a thin-walled cylinder and surrounded by the medium whose value of H with respect to the metal in question is to be determined. A source of heat in the form of a coil is then moved inside the tube at a rate which will practically produce a uniform temperature distribution in the thickness of the tube, and of sufficient intensity to bring the temperature of the tube to the desired maximum value. The temperature of the surrounding medium is kept at a constant temperature T_0.

By means of thermocouples spot-welded to the tube, the temperature at a given cross section of the latter is taken for three positions of the heat source as follows:

1 Position x_1, for which the temperature has reached the maximum value T_1.

2 Position x_2, preceding the position x_1 and for which the temperature had a given value $T_2 < T_1$.

3 Position x_2' following the position x_1, and for which the temperature has dropped back to the value T_2.

Calling g the thickness of the tube, the ratio of the perimeter P to the cross section A, entering Equations [23] and [24] is simply $1/g$ thus

$$\frac{T_2 - T_0}{T_1 - T_0} = e^{-[\sqrt{(\lambda v)^2 + H/g} - \lambda v](x_1 - x_2)} \qquad [102]$$

and

$$\frac{T_2 - T_0}{T_1 - T_0} = e^{-[\sqrt{(\lambda v)^2 + H/g} + \lambda v](x_2' - x_1)} \qquad [103]$$

These two equations can be rewritten in a more simple form by putting

$$\ln \frac{T_2 - T_0}{T_1 - T_0} = -m \qquad [104]$$

[9] Strictly speaking, coefficient 1.2 must also include the latent heat of fusion.

$$\frac{x_1 - x_2}{g} = u; \quad \frac{x_2' - x_1}{g} = u' \qquad [105]$$

hence

$$\frac{m}{u} = \sqrt{(\lambda vg)^2 + Hg} - \lambda vg \qquad [106]$$

and

$$\frac{m}{u'} = \sqrt{(\lambda vg)^2 + Hg} + \lambda vg \qquad [107]$$

Solving for λvg and Hg there follows

$$\lambda vg = \frac{m}{2}\left(\frac{1}{u'} - \frac{1}{u}\right) \qquad [108]$$

and

$$Hg = \frac{m^2}{uu'} \qquad [109]$$

hence finally the average diffusivity between the temperatures T_1 and T_2

$$\frac{1}{2\lambda} = \frac{4v}{m} \frac{(x_2' - x_1)(x_1 - x_2)}{(x_2 + x_2' - 2x_1)} \qquad [110]$$

and the average dissipation ratio between $(T_1 - T_0)$ and $(T_2 - T_0)$

$$H = \frac{m^2 \times g^2}{(x_2' - x_1)(x_1 - x_2)} \qquad [111]$$

Characteristically, the expression for diffusivity does not depend on the thickness of the tube and the expression of H does not depend on speed.

Control of Factors Governing Flame-Hardening and Continuous-Quenching of Steel Products. The purpose of flame-hardening is to produce a hardened case in steels of proper carbon and alloy content by raising the temperature of the case above the upper transformation point of steel Ac_3, and by quenching it as rapidly as possible in water. When dealing with parts of some length, such as gear rims or rails, the rise of temperature is accomplished by means of an oxyacetylene torch moving at a constant speed v, and the quenching, by a water sprinkler which moves closely behind the torch.

In what follows it will be assumed that the part has a rectangular section and that the flame of the oxyacetylene torch covers uniformly the surface over its whole width g, but that it extends over only a small portion l of its length. Thus the heat flow may be considered as being produced by a narrow plane source of heat moving at a constant speed, v. This case has been examined in Part 1, and Equations [51] and [60] have been derived to describe the temperature distribution around the heat source. Of these, Equation [51] represents an almost uniform rise of temperature which will result in the heated part throughout its thickness, at some distance behind the source, if there are no losses to the surrounding. This rise of temperature is then merely the consequence of the storing up of the heat, and if the latter is delivered at a rate of q thermal units per unit time, the rise of the temperature T_2 behind the source over the initial temperature T_0 is in accordance with Equation [51]

$$T_2 - T_0 = \frac{q}{c\rho agv} \qquad [112]$$

As previously $c\rho$ (c=specific heat, ρ=density) represents the volume specific heat, and v the speed at which the source moves. As for the symbols a and g, their previous meanings must be inverted in order to keep up with the present description of things.

They are accordingly; a = the thickness, and g = the width of the heated part.

As has been shown in Fig. 2, for the case of a very narrow plane source, T_2 also represents the temperature at some depth below the location of the heat source. This temperature is quickly approached by the bulk of the metal as the heat source moves away from the section considered. For convenience, temperature T_2 will be called the "bulk" temperature. With this in mind, Equation [60] represents the relative rise of the maximum surface temperature T_1, as compared to the rise of the bulk temperature of the piece. Fig. 18 shows the same relation graphically. Here for convenience the converse of the relative rise of temperature, namely $(T_2 - T_0)/(T_1 - T_0)$, has been plotted as a function of a dimensionless number λva, whose significance will be explained shortly, and for various lengths l of the source referred to the thickness a of the piece l/a. Assuming that in flame-hardening the surface temperature is required to reach a constant value T_1 and that T_0 is the practically constant room temperature, Fig. 18 shows that the higher the number λva the smaller will be the rise of the bulk temperature T_2. The same result is obtained by decreasing the relative length of the source l/a.

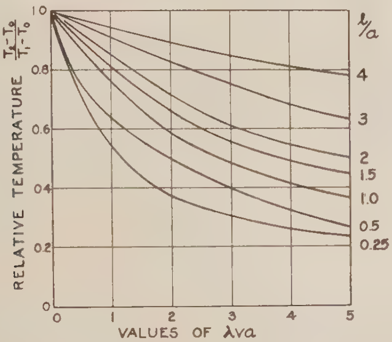

Fig. 18 Relation Between Rise of Surface Temperature T_1, and the Rise of Temperature of Bulk of Material T_2, for Various Conditions of Flame-Hardening

In order to interpret the number λva, attention is called to Equation [112]. If k is the heat conductivity of the material, it will be recalled that by definition

$$\frac{c\rho}{k} = 2\lambda \qquad [113]$$

hence Equation [112] can be rewritten as follows

$$\lambda va = \frac{q}{g} \times \frac{1}{2k(T_2 - T_0)} \qquad [114]$$

In this relation q/g is the rate of heat per unit width and it may be considered as a characteristic of the heat source employed. When comparing Equation [114] with the chart, Fig. 18, it is found that λva is a parameter which allows expression of the maximum surface temperature T_1, or the bulk temperature T_2, whichever is made variable, as a function of the heat characteristic (q/g) of the torch, and also another characteristic of the torch represented by the relative length l/a. Neither of these characteristics can be measured directly, but indirectly both can be determined by using Equation [114] and chart, Fig. 18, in reverse.

To this end, a trial experiment can be set up using a sample of the material to be treated in the form of a rectangular bar and measuring the temperature at a certain point of the surface and below the surface, while the latter is being heated, by passing over it the torch whose characteristics are to be determined. The following measurements are made:

1 Initial temperature, T_0.
2 Maximum temperature T_1 at the surface.
3 Temperature T_2, for which the surface temperature is almost the same as the depth temperature.
4 Speed of motion, v of the torch.
5 Width g, and thickness a of the bar.

Assuming an average constant value for λ and k, the value of q is thus determined from Equation [112] and the value of l from the chart, Fig. 18. For example, if $T_1 - T_0$ has been measured to be 800 C (1440 F) and $T_2 - T_0$ = 400 C (720 F), and if, furthermore, the speed at which the torch moved was 0.85 cm per sec, (0.336 ips), and the section of the bar 5 cm wide and 1 cm thick (about 2 × $^3/_8$ sq in.), then assuming, according to previous discussion, k = 0.08 cal per cm per deg C per sec, and λ = 6 sec per sq cm for steel, the value of q is found from Equation [114] as

$$q = 6 \times 0.85 \times 1 \times 5 \times 2 \times 0.08 \times 400 = 1640 \text{ cal per sec}$$

and l/a from the chart, Fig. 18, with $(T_2 - T_0)/(T_1 - T_0) = 0.5$ and $\lambda va = 5.1$, as 2; hence l = 2 cm (= 0.79 in.).

If each torch thus has been rated for a given value of $\bar{q}$ and l, it then becomes possible to determine for what thickness of steel it is best fitted. As a usual practice, it may be attempted to keep the maximum surface temperature slightly above Ac_3 and the bulk temperature slightly below Ac_1, thus the ratio $(T_2 - T_0)/(T_1 - T_0)$ will be around 0.66, and the value of λva, according to Equation [114] around 0.01 (q/g), if q/g is expressed in cal per cm per sec. Assume, for example, a torch is used for which q/g = 400 cal per cm per sec, and l = 2 cm. It is required to find the thickness a for which it is fitted and the speed of motion v.

From Equation [114] $\lambda va = 0.01 \times 400 = 4.00$ and from the chart, Fig. 18, the intersection of $(T_2 - T_0)/(T_1 - T_0) = 0.66$, and $\lambda va = 4$, gives $l/a = 3$. Thus $a = {}^2/_3$ cm = 0.26 in. and since $\lambda va = 4$, the speed v = 1 cm per sec, or about 23 ipm. If the bulk of the material is to be kept much below Ac_1, for example around 600 F, then $(T_2 - T_1)/(T_1 - T_0)$ is around 0.33 and $\lambda va = 0.005$ (q/g). Hence with the same type of torch as before, $\lambda va = 2$, and $l/a = 0.2$; $a = 2/0.2 = 10$ cm (4 in.). The speed, however, is reduced as much as the thickness has been increased, becoming only 1.5 ipm.

Continuous Quenching. If the heat, instead of being delivered to the piece, is being withdrawn at a rate of q thermal units per unit time, under conditions similar to that of flame-hardening, then Equation [114] and the chart, Fig. 18, can be used to control the final temperature T_2 to which the surface of a piece previously heated to a temperature T_0 will be automatically reheated after having been quenched down to the temperature T_1. This problem can be solved in a manner similar to that outlined for the flame-hardening. To make the conditions more specific, suppose it is desired to improve the hardness of the top surface of a rail by means of water-quenching, followed by tempering at 500 C (950 F). Using the theory of a moving-plane source, this treatment can be attempted in one continuous and single operation as follows: After the rail has left the rolling mill at some 980 C (1800 F), it is quenched by means of a water sprinkler moving at a constant speed v. The problem is then reduced to the determination of the characteristics of the water sprinkler in such a way that the surface of the rail after being quenched to the temperature of 20 C (86 F) is reheated to a bulk temperature of 500 C (950 F). To this end, suppose that the head of the rail is 2 in. wide and $1^1/_2$ in. thick, or approximately 5 × 4 sq cm, and that the heat content of the web can be neglected. Then by assuming that the water spray covers a surface of 5 × 5 sq cm, the value

of l/a is $5/4 = 1.25$. On the other hand, $(T_2 - T_0)/(T_1 - T_0) = \frac{500 - 980}{20 - 980} = 0.5$; hence from the chart, Fig. 18, $\lambda va = 3.2$. If this value is substituted in Equation [114], then by putting as previously $k = 0.08$ cal per cm per deg C per sec, and $\lambda = 6$ sec per sq cm, the value of q becomes

$$q = -3.2 \times 5 \times 0.16 \times 480 = -1240 \text{ cal per sec}$$

Since $\lambda va = 3.2$, the speed of motion is

$$v = 3.2/6 \times 4 = 0.132 \text{ cm per sec} = 3.15 \text{ ipm}$$

A similar computation will show that if it is desired to obtain a tempered martensite at 100 C (= 212 F) at the surface, the heat must be removed from the surface at a rate of 2280 cal per sec with the same speed of motion.

Before closing, emphasis again is put on the tentative character of the foregoing computation. There is obviously need for some preliminary experimentation before the theory expounded can be used as a practical tool much in the same way as this has been done for welding.

Appendix 1

Use of Instantaneous Sources for Solution of Heat Flow Due to Moving Sources

The solution of heat flow in an infinite solid due to a source moving in a given direction may be obtained by adding the contributions of an infinite number of small instantaneous sources placed one behind the other at infinitely small intervals of time, along the direction of motion. If the direction of motion is taken as the x-axis, then the contribution of an infinitesimal instantaneous point source dQ placed at a distance x' from the origin at a time t', may be represented as follows in so far as the increase of temperature dT of a point (x, y, z) at any moment $t \geqslant t'$ is concerned[10]

$$dT = \frac{\sqrt{2\lambda}\, dQ}{8\pi^{3/2}k} \times \frac{1}{(t-t')^{3/2}} \times e^{-\frac{\lambda}{2(t-t')}[(x-x')^2+y^2+z^2]}$$

where dQ is the quantity of heat of the point source, k is the heat conductivity, and 2λ is the converse of heat diffusivity. However, if the law of motion is given, x' is a known function of t'; and the same is true for the amount of heat delivered by the moving source; thus

$$Q = \phi(t') \text{ or } dQ = \phi'(t')dt'$$

and

$$x' = f(t')$$

hence

$$T - T_0 = \frac{\sqrt{2\lambda}}{8\pi^{3/2}k}\int_0^t \frac{\phi(t')}{(t-t')^{3/2}} e^{-\frac{\lambda}{2(t-t')}\left\{[x-f(t')]^2+y^2+z^2\right\}} dt' \quad \ldots\ldots\ldots [A]$$

This is the most general equation of heat flow in an infinite solid due to a moving-point source. Similar expressions can be derived for moving line and plane sources.

As a particular case, put

$$Q = qt'$$

and

$$x' = vt'$$

where q and v are constants.

Then Equation (A) becomes

$$T - T_0 = \frac{\sqrt{2\lambda}}{8\pi^{3/2}}\frac{q}{k}\int_0^t \frac{dt'}{(t-t')^{3/2}} e^{-\frac{\lambda}{2(t-t')}[(x-vt')^2+y^2+z^2]} \quad \ldots\ldots [B]$$

Put

$$t - t' = \tau^2;\ x - vt = \xi;\ \xi^2 + y^2 + z^2 = R^2$$

There follows

$$T - T_0 = -\frac{\sqrt{2\lambda}}{8\pi^{3/2}}\frac{q}{k}\int_0^t \frac{2\tau d\tau}{\tau^3} e^{-\frac{\lambda}{2\tau^2}[R^2+2v\xi\tau^2+v^2\tau^4]}$$

$$= \frac{\sqrt{2\lambda}}{4\pi^{3/2}}\frac{q}{k} e^{-\lambda v\xi}\int_0^t \frac{d\tau}{\tau^2} e^{-\frac{\lambda R^2}{2\tau^2}-\frac{\lambda\tau^2}{2}}$$

[10] Reference (9), p. 150.

or letting $t \longrightarrow \infty$

$$T - T_0 = \frac{\sqrt{2\lambda}}{4\pi^{3/2}}\frac{q}{k}\, e^{-\lambda v\xi}\int_0^\infty \frac{d\tau}{\tau^2}\, e^{-\frac{\lambda R^2}{2\tau^2}-\frac{\lambda\tau^2}{2}} \ldots\ldots [C]$$

The infinite integral appearing in Equation $[C]$ can be solved by means of the Bessel function $K_{1/2}(x)$. To this end put a new variable α, such that

$$\tau = \alpha R\sqrt{2\lambda} \ldots\ldots\ldots\ldots\ldots\ldots [D]$$

The substitution of Equation $[D]$ in Equation $[C]$ gives

$$T - T_0 = \frac{q\sqrt{2\lambda}}{4\pi^{3/2}\,k}\, e^{-\lambda v\xi} \times \frac{1}{R\sqrt{2\lambda}}\int_0^\infty e^{-(\lambda vR)^2\alpha^2-1/4\alpha^2}\,\alpha^{-2}d\alpha$$

But according to the theory of Bessel functions (10)

$$\int_0^\infty e^{-(\lambda vR)^2\alpha^2-1/4\alpha^2}\,\alpha^{-2}d\alpha = \sqrt{2\lambda R}\; K_{1/2}(\lambda vR)$$

and furthermore

$$K_{1/2}(\lambda vR) = \frac{\sqrt{\pi}}{\sqrt{2\lambda vR}}\, e^{-\lambda vR},$$

hence finally

$$T - T_0 = \frac{q}{4\pi k}\, e^{-\lambda v\xi}\,\frac{e^{-\lambda vR}}{R}$$

This expression has been derived previously in Part 1 in a more simple way for a three-dimensional case.

Using similar procedures for the line and plane instantaneous sources, Expressions [31] and [18] can be derived for the two-dimensional and linear heat flow, respectively.

Appendix 2

Expansion of Solution [45] in a Fourier Series

As shown by Carslaw,[11] if $f(y)$ is an even function of y which can be expanded, as also $f(y \pm 2na)$, in a Fourier series of cosines of multiples $\pi y/a$, then

$$\sum_{-\infty}^{\infty} f(y \pm 2na) = \frac{1}{a}\int_0^\infty f(y)dy + \frac{2}{a}\sum_1^\infty \cos\frac{\pi ny}{a} \int_0^\infty f(y')\cos\frac{\pi ny'}{a}\, dy$$

Let $f(y) = K_0(\lambda v\sqrt{\xi^2 + y^2})$, then

$$\sum_{-\infty}^{\infty} K_0\left(\lambda v\sqrt{\xi^2 + (y \pm 2na)^2}\right) = \frac{1}{a}\int_0^\infty K_0\left(\lambda v\sqrt{\xi^2 + y^2}\right) dy + \frac{2}{a}\sum_1^\infty \cos\frac{\pi ny}{a} \times \int_0^\infty K_0\left(\lambda v\sqrt{\xi^2 + y'^2}\right)\cos\frac{\pi ny'}{a}\, dy'$$

But, by virtue of the integral representation of Bessel function (10)

$$\int_0^\infty K_0\left(\lambda v\sqrt{\xi^2 + y^2}\right)dy = \frac{1}{\lambda v}\int_0^\infty e^{-(\lambda v\xi)^2t^2-1/4t^2}\,t^{-1}dt \times \int_0^\infty e^{-(\lambda vy)^2t^2}\,d(\lambda vy) = \frac{1}{\lambda v}\frac{\sqrt{\pi}}{2}\int_0^\infty e^{-(\lambda v\xi)^2t^2-1/4t^2}\,t^{-2}dt = \frac{\pi}{2\lambda v}\, e^{-\lambda v|\xi|}$$

Likewise

$$\int_0^\infty K_0\left(\lambda v\sqrt{\xi^2 + y'^2}\right)\cos\frac{\pi ny'}{a}\, dy' = \frac{1}{\lambda v}\int_0^\infty e^{-(\lambda v\xi)^2t^2-1/4t^2}\, t^{-1}dt \times \int_0^\infty e^{-(\lambda vy')^2t^2}\cos\left(\frac{\pi n}{\lambda va}\lambda vy'\right) d(\lambda vy')$$
$$= \frac{\sqrt{\pi}}{2\lambda v}\int_0^\infty e^{-(\lambda v\xi)^2-\mu_n^2/4t^2}\,t^{-2}dt = \frac{\pi}{2\lambda v\mu_n}\, e^{-\lambda v\mu_n|\xi|}$$

where
$$\mu_n = \sqrt{1 + \left(\frac{\pi n}{\lambda va}\right)^2}$$

hence recalling that

$$2\lambda = \frac{c\rho}{k}$$

we obtain expression, Equation [48] or [49], according to whether ξ is positive or negative.

Discussion

R. H. Cameron.[12] This paper is of considerable interest to the writer as a mathematician, because it shows that data of important practical significance can be calculated by the use of higher mathematics and higher mathematical techniques. While undoubtedly many of the author's conclusions have been or will be checked directly by experiment, his methods make it possible quickly to calculate data and plot curves which could be obtained directly only by a very large number of time-consuming and costly experiments. His theory of quasi-stationary states simplifies many practical problems to the point where calculation is possible and provides a method of attack on other problems which have not yet been put on a mathematical basis.

The author's technique changes a problem involving moving heat sources into one involving only fixed sources or singularities, and thus extends the classical methods of treating fixed sources to the more difficult problems of moving sources. These methods apply to such apparently diverse problems as arc welding, the rate of extrusion of a continuous casting, continuous quenching, and the heating effects of the passage of a bullet in a gun barrel.

Finally, his methods can be used in connection with experimental work to suggest the design of experiments, the direction they should take, and the interpretation of the results. His method for determining the values of diffusivity and heat-dissipation ratio is an example in point.

M. W. Rubesin[13] and R. C. Martinelli.[14] The author has presented an extremly interesting and useful contribution to the field of heat conduction. It is interesting to note that, due to the quasi-stationary state existing about the moving source, the method of relaxation can be readily applied to the problem.

A heat balance is made on a lattice of sides δ and depth $\delta/2$ situated directly below the moving source and moving with the source at a velocity v. Consideration is taken of the heat generated by the source, the heat conducted into the lattice by conduction, and the heat carried into the lattice by the movement of material through the lattice. Heat balances are made on other lattices surrounding the one about the source and a set of relaxation patterns established. Calculations show that the results of this numerical method check reasonably with the analytical results of the author.

Heat losses from the surface can also be accounted for by the method of relaxation.

Author's Closure

Professor Cameron's comments coming from a mathematician are very much appreciated. The technical man neither ignores nor belittles the value of the mathematics, but the thing he is primarily interested in is the final numerical value of the solution and not the way in which the latter has been obtained. Unfortunately, many a mathematician does not appreciate this point of view as fully as Professor Cameron does. They are inclined to consider the ultimate step of the analysis which consists of putting the solution in a form suitable for numerical computation as some sort of "puka" mathematics to be left to the computing machines. While the latter certainly are tremendous time savers, they hardly afford as complete a view of the problem as a mathematical analysis does, especially when it comes to the consideration of singularities. Some of the problems of heat flow require the use of the highest mathematical techniques, and it is only through the co-operation of mathematicians who are skilled in those techniques that a substantial progress in the theory of heat flow can be made.

The emphasis on the mathematical analysis does not preclude the use of numerical methods for particular applications. From this point of view the remarks made by Mr. Rubesin and Professor Martinelli are most welcome. The author is not enough familiar with the relaxation method to see the advantages that it offers in the treatment of a general problem of heat flow, like the one developed in the present paper, but he is aware of the possibilities which it affords in solving particular problems with specific boundary conditions. For example, he would be very much interested to see the discussers treat the following two problems which are of importance in arc welding:

1 Heat flow due to a moving plane source of a circular shape, and

2 Heat flow in a plate heated by a moving point source on one face and cooled by liquid medium on the other face.

The solution of the first problem may give a better insight into the phenomena of temperature distribution in the molten pool, and the second is of especial interest in ship-repair welding.

In closing the author wishes to thank all discussers for their kind interest in his paper.

Cutting Action of Reamers

By T. F. GITHENS,[1] CLEVELAND, OHIO

The cutting action of reamers resembles in many ways the cutting action of boring tools or twist drills. There is a common misconception that a reamer somehow gets into a hole and then scrapes the hole to size by means of its longitudinal cutting teeth. What really happens is that a reamer, a small amount larger than the hole to be finished, must cut its way into the hole by its entering teeth; and then produce a smoothly finished hole, round, straight, in proper alignment, and as near to the standard reamer size as possible. Reamers are provided with three kinds of clearance, point, peripheral, and longitudinal. Reamers can be made with combinations of positive, negative, and zero radial and axial rakes. The angle of the point and the feed per revolution affect the true rake angle of the cutting edge. Reamers must be kept sharp. The standard reamer made accurately to size and carefully used to produce a standard hole has been the most important factor in interchangeable manufacture. All classes of fit can be made by proper allowance on the shaft and the maintenance of the dependable standard hole produced by the standard reamers. These and other facts concerning reamers are explained in this paper.

Machine and Hand Reamers

A MACHINE reamer is a tool used for enlarging a hole, previously formed, and for freely cutting this hole as round, smooth, straight, in proper alignment, and as close to the standard or exact size as possible (1).[2]

A reamer is accomplishing its purpose when it cuts freely a round, smooth, straight hole its own size.

The principal parts of a machine reamer are shown in Fig. 1. These definitions and those for hand reamers are explained in the American Standard for Reamers (2).

The principal parts of a hand reamer are shown in Fig. 2.

Reamer Clearances

A reamer without clearance cannot cut because its cutting edges cannot get under the surface of the metal to lift or sever the chip from the metal. If forced into a hole it merely rubs or burnishes the surface of the hole and either heats the tool sufficiently to draw the temper, or tears the hole, or does both. A reamer having proper clearance cuts freely and smoothly (1).

There are three kinds of clearance on reamers, as follows:

1 Clearance on the entering ends of the teeth. This clearance is illustrated in Fig. 3 and is sometimes called "point" clearance.

2 Clearance along the lands or peripheral part of the reamer. This is sometimes called "radial relief" or clearance. This is illustrated in Fig. 5.

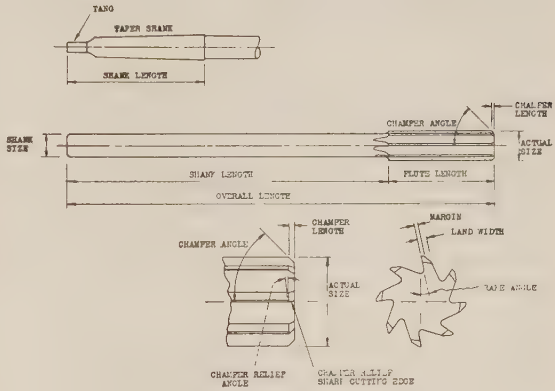

Fig. 1 Machine Reamer

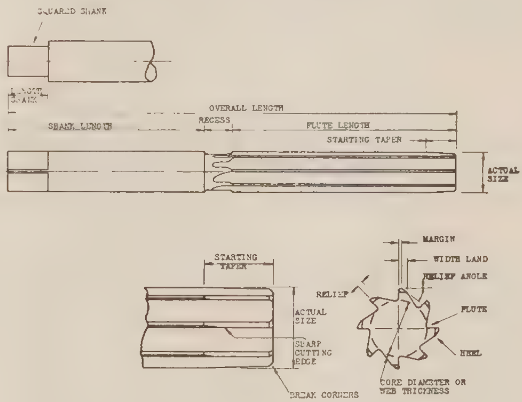

Fig. 2 Hand Reamer

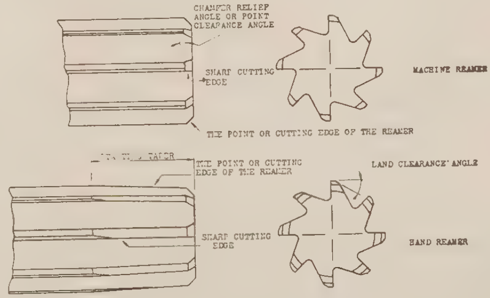

Fig. 3 Cutting Ends or Points, Showing Cutting Edges and Clearances

3 "Longitudinal relief" or "back taper," which is a very slight taper of about 0.0001 in., which makes the reamer smaller toward the shank in order to prevent the back end from enlarging the hole or dragging and thereby roughing up the finish of the hole, Fig. 7.

Point Clearance

The entering cutting edges on chucking reamers are usually beveled at an angle of from 40 to 50 deg for the purpose of keeping the extreme cutting corner as obtuse as possible, which helps to keep it sharp for a longer time. This cone shape also aids the reamer in centering itself in the work. These cone-shaped edges must be ground to a sharp edge with clearance for end-cutting, Fig. 3.

Hand reamers have a much longer taper, about 0.015 in. per in., and they are used for finishing purposes only. These reamers are but slightly smaller at the entering end, as it is necessary to remove only a small amount of metal in the finishing process. This long taper allows a scraping cut to be taken in such a manner that very accurate and smooth holes are produced. The taper edges must be ground to a sharp edge with clearance. A bevel of about 45 deg is also put at the long end of the tapering point to aid the hand reamer in entering the hole, but there should be so little stock left in the hole that this bevel should do no cutting, Fig. 3.

Fluted chucking reamers which are sometimes required for very accurate and smooth holes often have a slight second bevel in addition to that already mentioned, which acts like the taper on a hand reamer, thus making a smoother hole than would otherwise be the case. This is shown in Fig. 4; the length of this second taper need be only $^1/_{16}$ in. and must be ground to a sharp edge with proper clearance (1).

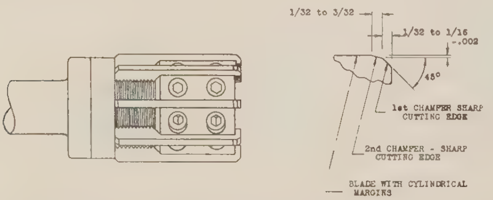

Fig. 4 Second Bevel on Point or Cutting Edges of Adjustable-Blade Reamers

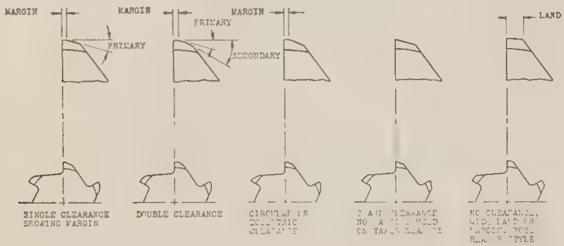

Fig. 5 Types of Side Clearance or Radial Relief

Side Clearance or Relief

Side clearance is illustrated in Fig. 5 and is formed by grinding away a portion of the land, usually leaving a slight cylindrical margin. The action of a reamer without side clearance is best understood by comparing a single tooth of the reamer with a boring tool having no clearance behind the cutting edge, as shown in Fig. 6, in which H is the hole to be bored, D the cutting edge, A is the side of the tool or peripheral land, with small sector B exactly concentric with the hole. Clearance is shown on the end of the boring tool at C.

It will be seen that great pressure would have to be exerted in the direction indicated by arrow X to hold the tool against the work, because the tool can cut the metal only at edge D, which enters the metal in the direction of the length of the hole, and therefore there is no cutting action accomplished by the part shown at B. This part only rubs and as there is some spring to the tool it does not cleanly sever the chip produced by cutting edge D. Therefore part B is forced outward at each succeeding revolution as the tool is advanced, which results in producing a tapering hole as shown on dotted line E. This could be overcome only by exerting enough pressure in the direction of arrow X to hold sector B absolutely to its line of travel and by having the surface so hard and smooth that it could not tear the wall of the hole (1).

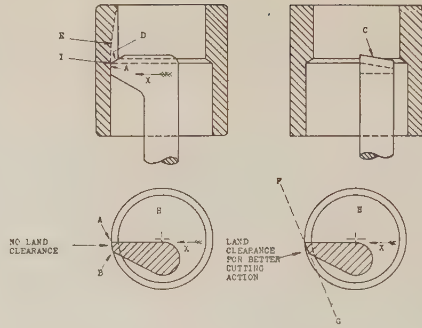

Fig. 6 Cutting Action of Boring Tool
(Land clearance improves performance.)

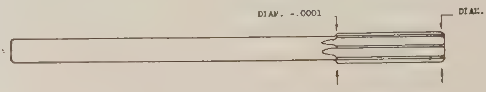

Fig. 7 Longitudinal Clearance or Back Taper

Another factor that also tends to produce a tapered hole and that requires additional pressure in the direction of the arrow is the dulling or rounding over of the extreme corner of the tool at 1. This dulling action is very severe at this point. The easiest and surest way to overcome these difficulties is to relieve the surface B along a line represented by FG. This reduces the required pressure in the direction shown by arrow X, and also lessens the trouble due to the dulling of the extreme cutting corner, and makes it possible to bore a hole the sides of which are practically parallel. The hole will also be smoother, as the side of the tool will scrape out the roughness left by the dulled corner as it follows after it. It must therefore be evident that a reamer without radial or side clearance is working under great difficulties and the chances for accurate work are small. It is also evident that as the surfaces of the reamer, which correspond to B, advance into the metal they should be lubricated and this can be done by lubricating the cutting edges as well.

Side relief is necessary for accurate reaming, yet a slight margin or cylindrical portion of the land must be left on the reamer to aid it to maintain correct size of the hole and allow the reamer to be sharpened many times without losing its original size. If the margin can be prevented from abrading or wearing away, the reamer can be sharpened back indefinitely. Of course some abrading and wear cannot be prevented, and commercial reamers are usually made a few ten-thousandths oversize so as to allow longer tool life and still produce accurate holes.

Rake Angles

The "rake angle" of a tool is the angle between the top cutting surface of a tool and a plane which is perpendicular to the surface of the work and to the direction of motion of the tool with respect to the work.

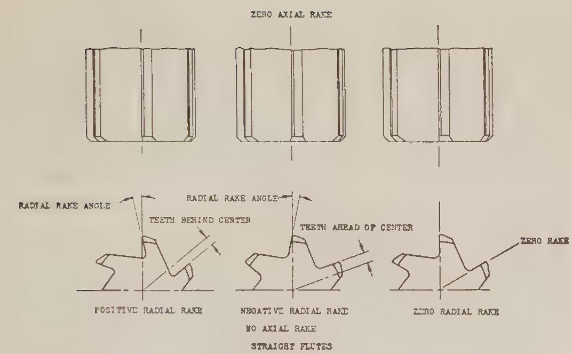

Fig. 8 Types of Radial and Axial Rake

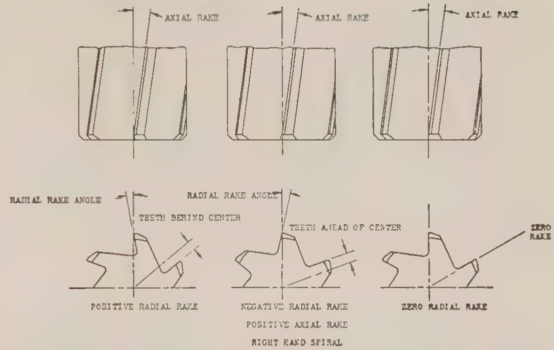

Fig. 9 Types of Radial and Axial Rake

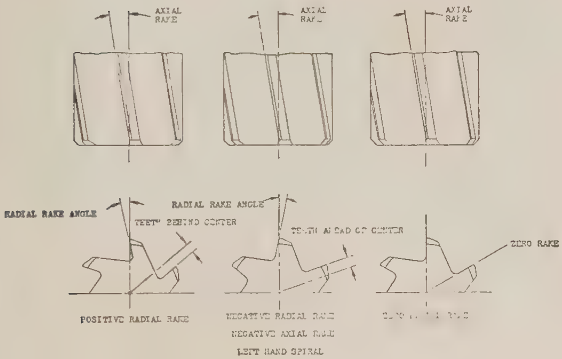

Fig. 10 Types of Radial and Axial Rake

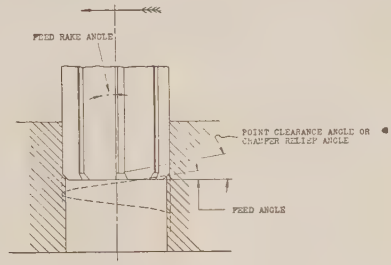

Fig. 11 Rake Angle Due to Feed

(The angle that the reamer makes with the work as it feeds into the hole. Point clearance angle or chamfer relief angle should be greater than the feed angle shown. The action of the feed increases the rake angle of the reamer by the amount shown by the "feed-rake angle.")

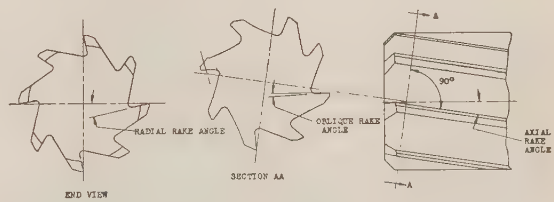

Fig. 12 Rake Angle Normal to Helix Angle or Oblique Rake Angle

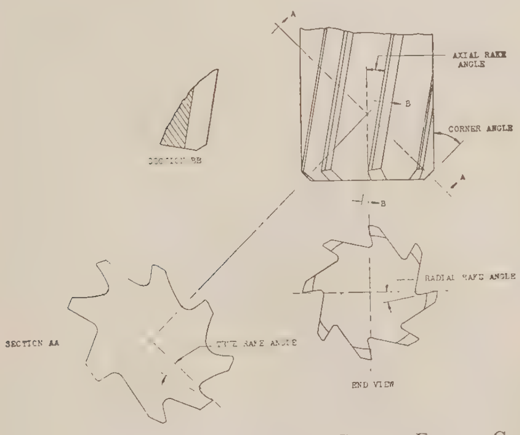

Fig. 13 True Rake Angle, Normal to Cutting Edge of Chamfer, Resulting From a Given Combination of Radial-Rake Angle, Axial-Rake Angle, and Corner Angle or Point Chamfer

The "axial-rake" angle is the same as the "helix angle." The "radial-rake" angle is the angle between the face of the flute and a radial line drawn to edge of the margin.

The best rake angle for each material, speed, feed, and machine-operating condition is a matter of trial and experiment.

Figs. 8, 9, and 10 show some possible combinations of axial and radial rakes with which reamers can be made.

Fig. 11 shows that the manner in which the reamer approaches

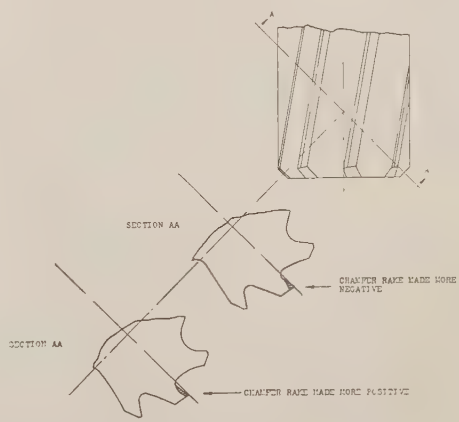

Fig. 14 Positive or Negative Rake May Be Varied on Cutting Edges of Chamfer

the work affects the rake angle. The larger the feed per revolution the larger is the rake angle due to the feed.

Fig. 12 shows how the axial- and radial-rake angles combine to affect the oblique rake angle shown (3).

Fig. 13 shows a section at right angles to the point cutting edge at the actual and cutting edge of the reamer. This true rake angle depends upon the combined values of the radial rake, the axial rake, and the point angle or bevel.

Fig. 14 shows how in special cases with great care in grinding, the cutting rake of the point cutting edges may be varied for different materials and cutting conditions.

Form of Flutes

The style of flute is of the greatest importance, as its shape and area determine the relative strength of the tooth and the ability to carry away the chips. Large chip space and strength are desirable in all reamers but they are of greater importance in reamers designed for taper-reaming and for use in machines. The cutting face of a reamer tooth should have a fillet, see Fig. 15,

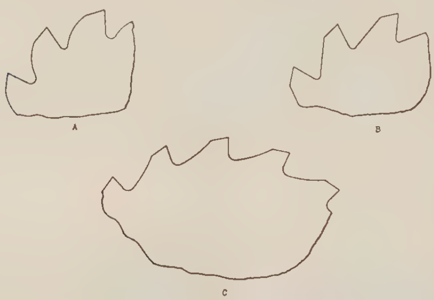

Fig. 15 Different Forms of Flutes Used for Various Types of Reamers

beginning about midway between the top and bottom of the tooth where great strength is desired, as in machine reamers, and nearer the bottom where the strength is of less importance, as in hand reamers. This fillet does not reduce the chip area materially because the chips tend to curl in most metals and this curl conforms to the shape of the fillet. Theoretically, the shape of the back of the tooth should be a convex parabola from the cutting edge to the base or junction of the fillet to obtain maximum strength. For manufacturing reasons a straight line or a concave curve which is tangent to the fillet and which lies outside the parabola is standard practice.

At A in Fig. 15 is shown a tooth with convex parabolic flank which is rarely used except on heavy chucking reamers where the cuts are heavy; at B is shown the straight flank; while at C is shown the concave-curve flank largely used by most manufacturers. Shape C provides a large chip area, and where uneven spacing is practiced the lands are most easily kept at uniform width (1).

Prevention of Chatter

Another desirable feature in a reamer, and especially a taper or hand reamer, is that it be able to cut a round smooth hole without chattering. There is an erroneous opinion prevalent that an even number of flutes chatter more than an odd number. This is a fallacy and our experience shows that an odd number of flutes will chatter as readily as an even number, especially when the reamer has more than four flutes.

Chatter may sometimes be eliminated by reducing the amount of clearance. To make reamers suitable for reaming most kinds of material met with in ordinary practice a considerable amount of clearance must be given, and this would produce chatter by biting in unless it is offset by some other features.

Chatter may sometimes be reduced by making the setup as rigid and strong as possible and by using pilots and guide bushings.

Chatter may also be reduced by cutting down the speed of the reamer. Speeds must not be so high as to permit chatter (5). Too low a feed may in some cases cause chatter due to glazing of the hole. Too much positive rake angle or too much negative rake angle may also cause chatter.

Reamers as commercially made usually have the cutting teeth unequally spaced. Fig. 16 shows a reamer with even spacing and a reamer with one type of uneven spacing. The reason for providing this uneven spacing is to reduce the possibility of chatter.

Fig. 17 shows a chucking reamer about to enter a hole. If the axis of rotation A-A of the reamer is exactly in line with the axis of the hole B-B, and all cutting conditions correct, such as speed not too high, feed not too low, amount of stock sufficient for a chip, rake not too hooked or too negative, the work and reamer rigidly held and guided if possible, there should be no chatter and a round, smooth, accurately sized hole should be produced.

However, if the axis of the reamer is out of line with the axis of the hole, or if a hard spot in the steel is cut, or if the reamer teeth are not sharpened accurately so that they are all at the same angle and length; one tooth of the reamer may cut a little deeper than the others, and in addition to the motion of rotation about its axis, the reamer will also acquire a secondary form of rotation as shown in Fig. 18.

This shows the situation greatly exaggerated. Tooth 1 has cut deeply into the metal and for an instant the reamer will rotate about the instantaneous center 1, until tooth 2 bites into the metal. Tooth 2 now becomes the instantaneous center of rota-

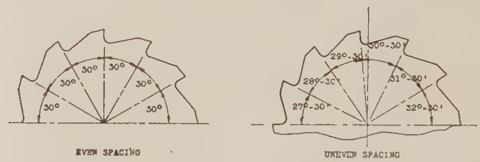

Fig. 16 Unequal Spacing of Flutes to Avoid Chatter

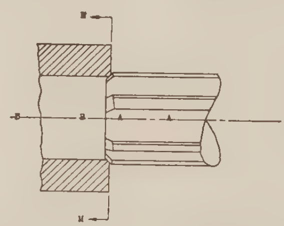

Fig. 17 Unequal Spacing of Flutes to Avoid Chatter

Fig. 18 (*left*) Unequal Spacing of Flutes to Avoid Chatter
(Section M-M of Fig. 17 greatly exaggerated. Reamer while rotating about its axis rotates also about center 1, a small amount, until tooth 2 cuts.)

Fig. 19 (*right*) Unequal Spacing of Flutes to Avoid Chatter
(Section M-M of Fig. 17 greatly exaggerated. Reamer while rotating about its axis rotates also about center 2, a small amount, until tooth 3 cuts.)

tion (see Fig. 19) and the reamer rotates until tooth 3 bites in, and so on all around the reamer. This continues while the reamer is rotating about its axis. A very bad condition such as described would result in chatter. If the teeth are unevenly spaced so that the distances between 1 and 2, 2 and 3, etc., are not the same, the jump or biting-in of the teeth will be unevenly distributed, and the cut gradually may become smooth and chatterless.

Cutting Action

The cutting action of a reamer has been shown in Fig. 6 to be similar in many respects to that of a boring tool. In Fig. 20 is shown a boring tool about to enlarge or finish-cut a rough hole. It must cut it sway into the hole by its sharp, cleared, end cutting edge *D*. Similarly the reamer must cut its way into the small rough hole by its sharp, cleared, end cutting beveled teeth or point.

The cutting action of a reamer is in some respects similar to that of a drill. Fig. 21 shows a drill about to cut through and enlarge a rough hole. The drill is larger than the rough hole and in order to enter, the drill must cut its way in. Similarly, in the same figure the reamer must be larger than the rough hole and must cut its way into the hole by its end cutting or beveled teeth. The cutting action of the longitudinal margins or lands is explained in connection with Fig. 6.

Fig. 22 shows the similarity of the cutting action of a drill and a hand reamer. The cutting action of a reamer is in some respects similar to that of an end mill as shown in Fig. 23, assuming that the direction of feed for both tools is helically axial.

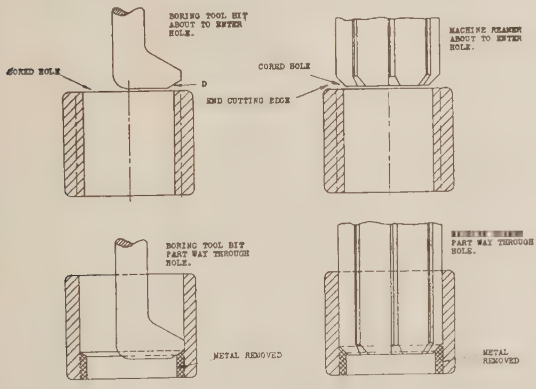

Fig. 20 Similarity of Cutting Action of a Boring-Tool Bit and a Reamer

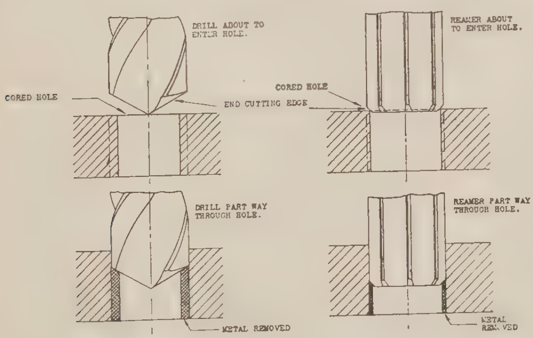

Fig. 21 Similarity of Cutting Action of a Twist Drill and a Machine Reamer

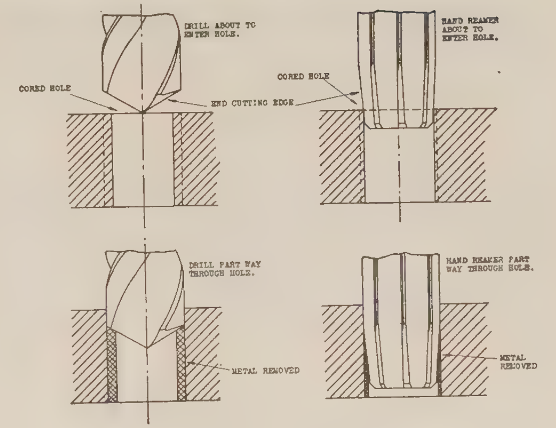

Fig. 22 Similarity of Cutting Action of a Twist Drill and a Hand Reamer

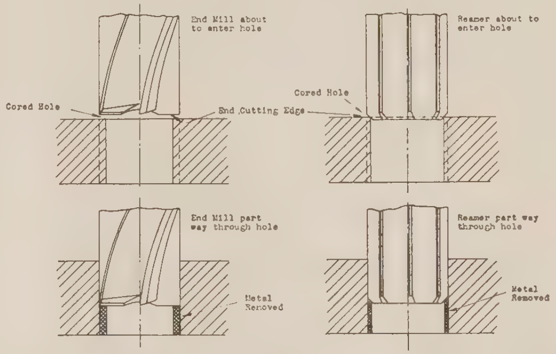

Fig. 23 Similarity of Cutting Action of an End Mill and a Machine Reamer

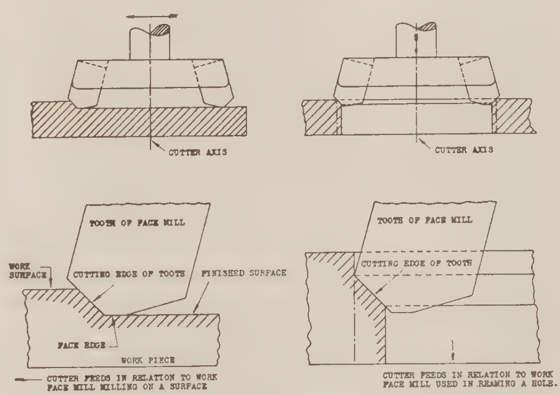

Fig. 24 Similarity of Cutting Action of a Face Mill and a Machine Reamer

The bodies of both tools fit in the holes they cut. Of course, in an end mill the direction of feed is usually perpendicular to the axis of the tool, not along the axis. Also an end mill will not usually produce as accurate a hole as a reamer because its longitudinal teeth are backed off sharp with no margins or lands.

Fig. 24 shows how a face mill, usually used for cutting along the surface of a piece of work, might be used to enlarge a hole.

This shows that the cutting action of face-milling teeth is essentially similar to that of reamer end cutting teeth. The lands or margins on a reamer serve the same purpose of smoothing the cut that the faces do on a face mill.

Reamer Sharpening

After a reamer has been used for a number of holes it will show signs of wear. These signs should be carefully watched and studied and at the proper time the reamer should be resharpened. In general, higher speeds will cause the reamer to dull faster, but higher speeds also give higher production. The finish required also determines the speed possible.

It will be noticed that the reamer will become dull along its once sharp edges *A-B*, Figs. 25 and 27, with the greatest wear at the corners *A*. After a number of holes have been reamed the corner *A* will become completely rounded off. If the reamer is continued in use after this corner has become worn, the sharp edge along the margin *A-C* will also become worn and abraded starting at *A* and working back along the margin or land *A-C*. If the reamer is kept in use in this dull condition it will be completely ruined, the margins all the way back to *D* will become abraded, and the reamer cannot ream a smooth hole to the correct size.

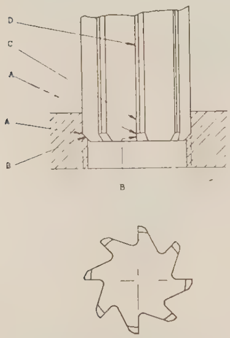

Fig. 25 Wear of Reamer Cutting Edges

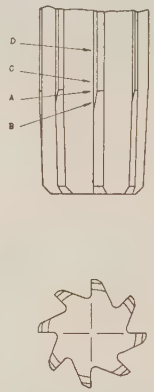

Fig. 27 Wear of Hand-Reamer Cutting Edges

The first result of using a dull reamer will probably be undersize holes, the reamer will be actually forced through the hole without cutting its true size. This of course, causes unnecessary wear on the reamer lands. If at the first sign of holes coming smaller in size the reamer is sharpened, holes up to size will be again produced.

To sharpen the reamer it is necessary to grind only the point or cutting edges back as shown at *A-D*, Figs. 26 and 28, with the proper clearance. The edges are ground back until the corner and marginal dullness between *A* and *C* is removed.

The importance of frequent reamer point sharpening for accurate and smooth holes cannot be overemphasized, especially as it is as simple an operation as drill point sharpening, and a very similar one. Frequent sharpening prolongs the life of the accurately sized reamer margins and lands, and guards against their abrading or wearing undersize and producing undersize holes.

Just how often a reamer should be sharpened or what tool life a reamer should have in minutes of use per grind or number of inches of holes reamed per grind must be determined by trial for each particular application.

In general, the higher the cutting speed the shorter will be the tool life, but of course the high cutting speed has the advantage of high production, if the finish and accuracy of the holes produced are satisfactory.

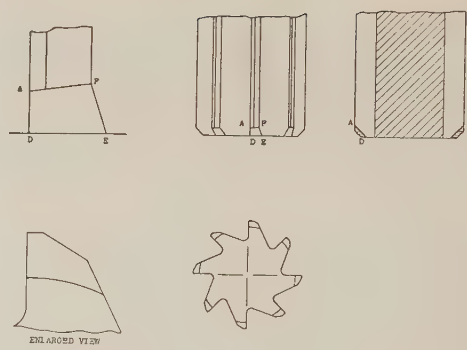

Fig. 26 Sharpening of Reamer-Point Cutting Edge

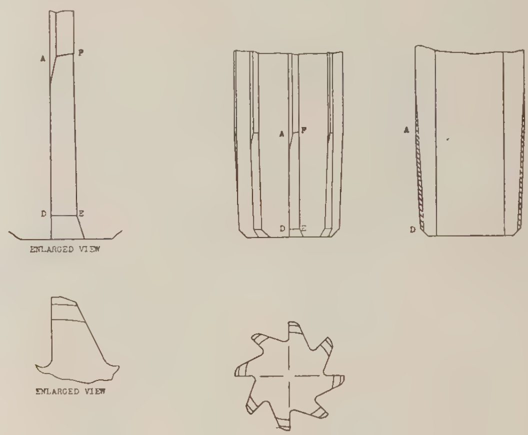

Fig. 28 Sharpening of Hand-Reamer Point Cutting Edge

On single-operation machines where it is a simple matter to take out a tool and resharpen it, low tool life and high production are desirable. On a multispindle automatic it might be uneconomical to change tools more than once a shift, and here slower speeds and longer tool life on a particular operation may be better.

In any case, the use of a dull tool is very poor economy. It is destructive of the reamer and productive of poor and unaccepta-

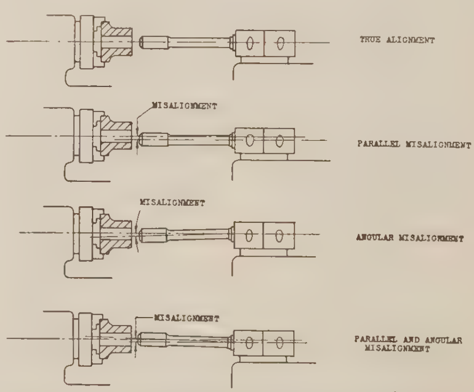

Fig. 29 Floating Toolholders and Alignment

ble work. Some methods for sharpening reamers are shown in Fig. 28.

Floating Toolholders

It should always be borne in mind that a reamer produces its best work when taking light cuts. If the holes are being finish-reamed in a machine, good work has been done by holding the reamer in a chuck, collet, or holder that will float smoothly without jumping. Some good work is done with holders that allow the reamer to float perpendicular to its axis as well as at an angle (1). This floating action is necessary because it is almost impossible to hold the reamer so that it is exactly concentric with the hole, and at the same time have the line of travel of the axis of the reamer coincide or line up with the axis of the hole. A reamer must align itself with the hole it is cutting for extreme precision. The lands or margins of the reamer must be a snug fit in the hole that the reamer is finishing. The axis of the rotating reamer must coincide within a very small amount with the axis of the tool.

This floating alignment and rigidity of cut are both difficult to attain but are necessary for good work.

Speeds, Feeds, and Lubricants

No definite rules can be given to cover the speeds and feeds that should be used in reaming. Several factors govern the correct feed and speed. The material to be reamed and the material of the reamer are perhaps the most important governing factors. The finish desired in the hole and whether hand feed or machine feed is used, govern the selection of the proper feed. The type of lubricant used, or whether the reamer is piloted or guided in any way, also influence the decision.

In general, reamers should be run at about one half to two thirds the speed of the corresponding drill. It is always best to start the reamer somewhat slower than this, and gradually increase the speed until the best condition is found. If the reamer is run at too slow a speed the production will suffer, while if run too fast, the wear on the reamer will dull it too soon. Somewhere between these two extremes is the proper speed which gives a high productivity with a long reamer life.

Feeds should be from 2 to 3 times the feed of the corresponding drill. The higher feed causes increased production and reduced tool wear. If too fine a feed is used, the reamer will be subjected to unnecessary wear. Too coarse a feed will produce feed marks in the hole. The desired finish must be balanced against the production per hour.

Feeds are governed by the size of the reamer and the material reamed. A general rule is first to try a feed of 0.002 to 0.004 in. per revolution for reamers smaller than $^1/_8$ in.; 0.004 to 0.008 for reamers $^1/_8$ to $^1/_4$ in.; 0.008 to 0.014 for reamers $^1/_4$ to $^1/_2$ in.; 0.014 to 0.030 for reamers $^1/_2$ to 1 in.; and 0.030 to 0.050 for reamers larger than 1 in. Alloy and hard steels should generally be reamed with the lighter feeds, while cast iron, brass, and aluminum are sometimes reamed with the heavier feeds. Suggested speeds for reamers are given in Table 1.

TABLE 1 SUGGESTED SPEEDS FOR HIGH-SPEED REAMERS

Material reamed	Speed, fpm
Aluminum and its alloys	130–200
Bakelite	70–100
Brass and bronze, ordinary	130–200
Bronze, high-tensile	50–70
Cast iron, soft	70–100
Cast iron, hard	50–70
Cast iron, chilled	20–30
Malleable iron	50–60
Magnesium and its alloys	170–300
Monel metal	20–30
Steel, machinery (0.2 to 0.3C)	50–70
Steel, annealed (0.4 to 0.5C)	40–50
Steel, tool (1.2C)	30–40
Steel, forgings	30–40
Steel, alloy	30–50
Steel, stainless, free-machining	40–50
Steel, stainless, hard	20–30

Lubricants

Lubricants have many functions, several of which are as follows:

1 To cool both the cutting edges of the tool and the work being machined. This can best be done by directing as large a volume of the coolant as possible on the cutting edges. On thin-walled work it often helps to allow a large volume of flow onto and around the piece.

2 To lubricate the chips; this aids in chip clearance.

3 To improve the finish of the work. The selection and proper application of the lubricant will materially influence the machined finish.

It is suggested that lubrication problems be referred to a reputable manufacturer of cutting oils. The following list of lubricants should be used as suggestions only:

1 Aluminum and its alloys: Soluble oil, kerosene, and lard-oil compounds, light nonviscous neutral oil, kerosene, and soluble-oil mixtures.

2 Brass: Dry, soluble oil, kerosene, and lard-oil compounds, light nonviscous neutral oil.

3 Copper: Soluble oil, winter-strained lard oil, oleic-acid compounds.

4 Cast iron: Dry or with a jet of compressed air for a cooling medium.

5 Malleable iron: Soluble oil, nonviscous neutral oil.

6 Monel metal: Soluble oil, sulphurized mineral oil.

7 Steel, ordinary: Soluble oil, sulphurized oil, high E.P. value mineral oil.

8 Steel, very hard and refractory: Soluble oil, sulphurized oil, turpentine.

9 Steel, stainless: Soluble oil, sulphurized mineral oil.

10 Wrought iron: Soluble oil, sulphurized oil, high animal-oil-content mineral-oil compound.

Regular Reamers and Basic Standard-Hole System of Tolerances

Varying degrees of accuracy result from the use of different tools employed in the drilling, boring, and reaming of holes. The cost of obtaining the accuracy required by some kinds of work would be prohibitive for others. Therefore the proper tools for producing holes in any class of work are those best adapted to produce the required accuracy from the standpoint of an over-all economy. By an over-all economy is meant the greatest number of suitably finished holes that can be produced for each dollar paid out for tools, labor, and machine expense.

Drilled holes are neither round, straight, nor of uniform diameter when compared with the accurate holes required by most industries, although they may be sufficiently accurate to meet the requirements of holes for rough bolts, rivets, and similar classes of work. When a close fit is required holes are usually finished by reaming. When holes of extreme accuracy are required it is necessary to use two reamers in order to obtain the desired results. For all such work as holes for pins, rods, or finished bolts, one reaming operation is sufficient, and even in many grades of machines the holes for journals are finished with a single machine-reaming operation. Before selecting a type of reamer for any class of work, it is advisable to study the cutting action of different reamers in order to select the one best adapted to each class.

In some shops the practice is to produce round, smooth, straight holes, as close to the standard or exact size as possible. All the tolerance or allowable error is above the basic or exact size. In other words, the hole must be slightly oversize, not

undersize. This enables holes to be produced in large numbers, which are sure to make the proper fits. Many shops insist that all holes in parts belonging to good work must be hand-reamed, and in such a manner that the work is subjected to no distortion due to holding or clamping. This is sometimes done by holding the hand reamer in a vise and passing the work over the reamer with a screwlike motion, the reamer scraping only a few thousandths out of the hole. Other shops insist that the holes be finished on the chucking machine, and in this case the chucking reamers must be accurate and the work not distorted by the chuck if good results are to be expected.

The standard reamer and the standard basic plug-and-ring gage have been the foundation of interchangeable manufacturing.

A standard basic 1-in. hole may be defined as one which will just receive a 1-in. plug gage which measures exactly 1 in. diam as measured on a measuring machine. The hole which receives this plug gage will also receive an accurately finished shaft of the same size (4).

In practical manufacturing the "go" gage is not usually exactly 1 in. diam but has a plus wear allowance and a plus manufacturing tolerance, which means that the basic hole in practical manufacturing is slightly large.

Commercial reamers are made slightly oversize because the hole made by the reamer must be large enough to receive the "go" working gage. Reamers as made commercially have also a slight plus wear allowance and a slight plus manufacturing tolerance (2). This assures that all holes carefully reamed as near to the exact size of the reamer as possible will all accept standard commercial "go" plug gages and will all receive finished shafts made to the correct sizes, with proper allowances between hole and shaft depending upon the class of fit wanted.

Many parts made by interchangeable mass-production methods depend upon the precision and uniformity of the reamer sizes to maintain hole sizes which will be basic, with a very small tolerance oversize. The holes are sure to be large enough and yet not too large to produce undesirable results.

American Standard for Allowances, Tolerances, and Gages for Metal Fits

Since 1926 the foregoing standard has been in use as a guide for the correct dimensions of holes made for interchangeable manufacturing.

This standard is based upon the same principles as the successful American Standard for Screw Threads ASA B1.1-1935. These are the same dimensions as published in Handbook H-28 Screw Thread Standards for Federal Services.

In both of these standards the minimum hole is taken as the basic or standard size. This means that the interference point or place where metal-to-metal fit occurs between hole and shaft will be at this basic dimension no matter what class of fit is specified. This is illustrated in Figs. 30 and 31.

The advantage of the standard-hole system is that it enables standard basic plug gages to be carried in stock and establishes definite minimum hole sizes, below which the holes cannot go, and maintains universal interchangeability.

If it is necessary to change tolerances or allowances on a given fit, this can be done in the basic-hole system without changing the "zero," "base," or "interference line," as the minimum hole is left constant, and the maximum hole, or minimum or maximum shaft sizes are changed. The standard plug gage always rejects any hole below basic size which might destroy interchangeability.

It is easier to produce plug gages, blocks, and measuring rods to high grades of precision, for use in measuring hole members than it is to produce gages for measuring shaft members. Hole members are best measured with fixed-size gages and also are best produced with fixed-size or solid reamers, or broaches. Shaft

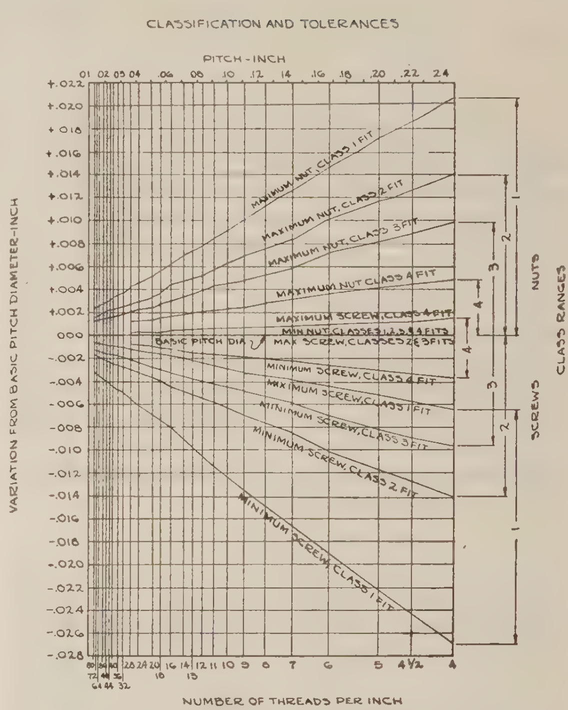

Fig. 30 Relation of Maximum and Minimum Pitch Diameters of Classes 1, 2, 3, and 4 Fits to Basic Pitch Diameters

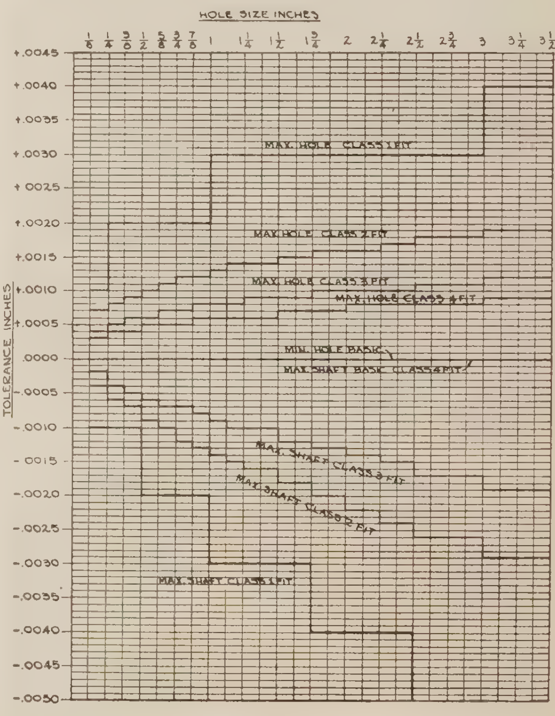

Fig. 31 Basic Minimum Hole for All Classes of Fits (American Standards Association.)

members are more easily measured with adjustable gages and also more easily produced with adjustable tools such as lathe tools or grinding wheels. Changes in allowances or tolerances for various fits can thus be more readily made on the shaft member than on the hole member.

Fig. 32 shows how a standard commercial reamer would produce holes of any class of fit desired, if the reamer were carefully used so as to cut close to its exact size. Also, if properly sharpened and cared for, a long life of the reamer may be obtained before its lands are worn so undersize that the reamer will produce holes below the minimum size.

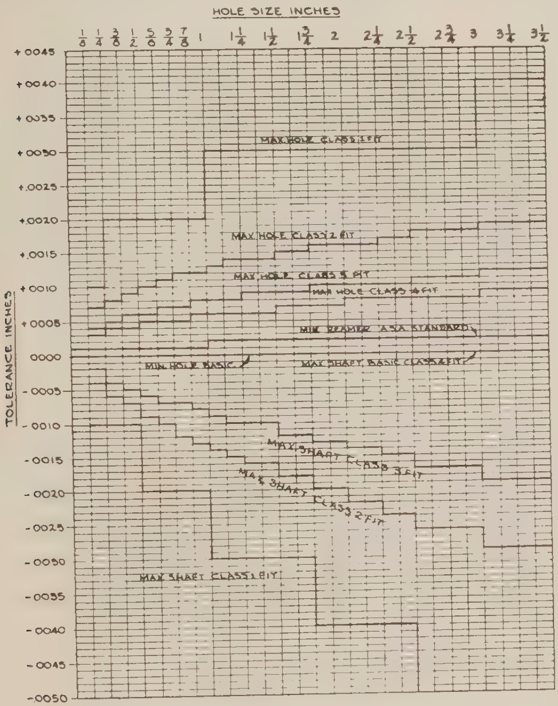

Fig. 32 Standard Reamer to Produce Standard Holes of All Classes of Fits

Another advantage of the basic-hole system of fits is that it allows one standard-size reamer with definite tolerances to be carried in stock throughout industry for the convenience of the customer and user. These reamers will produce universal interchangeable work for any of the classes of fit.

The fact that the reamer is accurately sharpened to size is no guarantee that the hole made will be as accurate as the reamer. The accuracy of the hole depends upon many factors, such as hand- or machine-reaming, machinery and fixture in good condition or badly worn, the kind of material reamed, the kind of lubricant, and the skill and carefulness of the mechanic.

It was to take care of this great variety of working conditions that different tolerances were put on the various classes of standard holes in the report of Allowances and Tolerances of the American Standards Association, ASA B4a-1925.

It was realized by the committee which wrote this report that the one standard-size reamer will produce holes of varying tolerances depending upon the conditions of its use. Extreme accuracy and precision are usually expensive, and it is uneconomical to make a hole perfect when one not so good will serve the purpose just as well. Therefore the various classes of holes and fits were provided as a measure of economy. It was intended all along, however, that but one standard size of reamer would be necessary; careful use of this reamer would produce a Class 3 or 4 hole; rough, rapid, or worn machine use would produce a Class 1 hole.

It has sometimes been thought that large tolerances were put on rough holes to allow for wear on the reamer, whereas the large tolerances are really there to indicate that costly tooling and hand-finishing are not necessary when an inexpensive rapid job is sufficient for the purpose.

Long wear life of the reamer will be obtained by keeping the point sharp and the lands in good condition rather than by using an oversize reamer which will produce holes that are too large.

It has sometimes been suggested that the American Standard for Tolerances, Allowances, and Gages for Metal Fits should contain a basic-shaft standard as well as the present basic-hole standard. It is believed that it would be better not to do this because it would imply the standardizing and carrying in stock of a different minimum or basic plug gage for each class of fit for each nominal size of hole, Fig. 33. Also it would imply the use of a different-size reamer for each class of fit. These solid tools are difficult to produce and expensive to maintain. It is more eco-

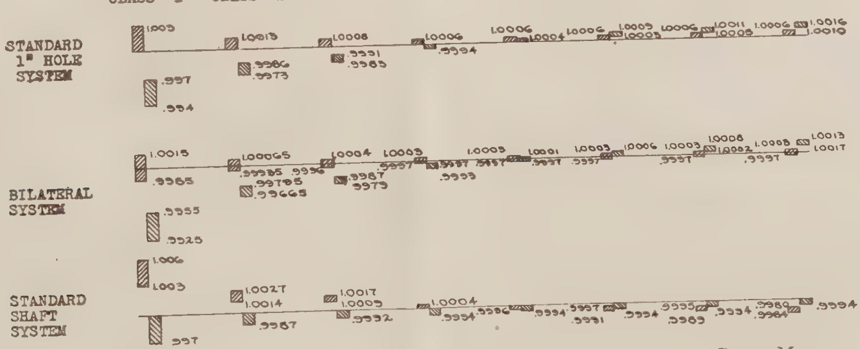

Fig. 33 Standard-Hole System Uses One Standard Basic-Size Plug Gage to Check Minimum Hole Size for All Classes of Fits

(Sketch made to show that standard-hole system uses the one standard basic-size plug gage to check minimum hole size for all classes of fits. This means that interchangeability is positively maintained for any allowance between hole and shaft and any tolerance on shaft. The "zero line," "interference line," or "metal-to-metal fit contact line" is always at the basic dimension, always at the standard minimum hole. Standard stock reamers, if carefully used and maintained sharp, will produce these standard holes for a long period of reamer-wear life.)

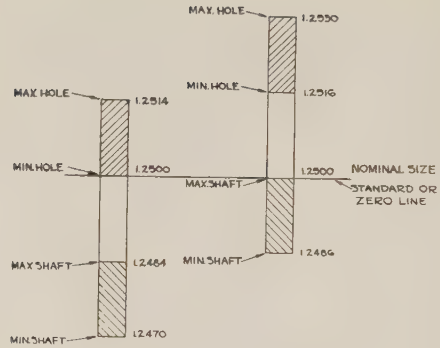

Fig. 34 Hole Sizes for Standard-Hole and Standard-Shaft Systems

nomical to obtain various classes of fit by maintaining standard holes and varying the shaft dimensions.

If for some particular reason it is found better to use the maximum size of the shaft as standard, as shown in Fig. 34, the size of hole becomes special and special drills and reamers must be obtained. Special tools are always more costly than the regular and also require longer waits for deliveries. As there is less use for a special tool, it lies in the toolroom for a longer time unused, and the overhead of manufacturing is increased.

For example, in Fig. 31 a standard shaft system of fit calls for 1.2500 as the maximum shaft size and 1.2516 as the minimum hole size. This can be considered the same as a basic-hole system of fits using a "special size" 1.2516 as the basic hole. This (as all standard shaft fits do) requires special-size reamers. From the tables of allowances and tolerances the maximum and minimum shafts and holes are easily found for special as well as standard sizes. In other words, the holes of the "standard-shaft" system, are nothing but "special" holes of the standard-hole system. The standard shaft system is really a special, nonstandard use of the standard-hole system.

In this connection E. C. Peck (1) states: "I see no need whatever for a basic shaft standard. The only example I have ever heard given is the one where two free fits are required on the ends of the shaft and a force or tight fit wanted in the center, and this has been done economically and satisfactorily for years by the 'basic-hole system.' All during World War I, I saw the drawings for millions of interchangeable parts, and I never saw any that were not made to the 'basic-hole' system."

Thus the publishing of special tables for the standard shaft system is unnecessary, as all the values for tolerances and allowances may be taken from the Standard Hole System of tables, merely by basing all the fits on the minimum-size hole.

Conclusions

A reamer is a cutting tool and like other cutting tools it must be provided with correct clearances, rakes, and other features of good tool design. Its cutting edges must be sharpened frequently to prolong the useful life of the tool and to produce accurately smoothly finished holes.

The standard reamer made with standard manufacturers' tolerance is one of the most important tools used by the interchangeable production manufacturers.

The standard reamer is an important feature of the standard-hole system of allowances and tolerances for metal fits and provides the most economical method of securing precision fits and universal interchangeability.

Utilization of Producer Gas in Industrial Furnaces

By D. B. HENDRYX,[1] PITTSBURGH, PA.

Producer gas is the cheapest artificial fuel per Btu that can be made from solid fuel. This paper discusses the economics, the equipment, and methods of generating producer gas for industrial uses.

MOST gas-producer projects look good on paper. The basic idea of a low-cost gaseous fuel, made from coal at a central point and distributed in pipes to the furnaces, is excellent and attractive.

Producer gas for industrial uses only is discussed in this paper, as contrasted to gas manufactured for public-service distribution. It is made from coal or coke, and the solid fuel is completely transformed into gas in the process. Producer gas is the cheapest artificial fuel per Btu that can be made from solid fuel.

Comparative Cost of Fuels

The economics of the fuel situation must be considered first. The cost of fuels can be compared on a Btu basis, but this must be the total cost of heat delivered to the furnace, including fuel and ash handling, power, steam, depreciation, etc. In most industrial districts, coal is the cheapest fuel, but for various reasons it frequently cannot be used in furnaces in its crude form, either on grates or as pulverized fuel. Such considerations as furnace temperature and atmosphere, reversing and regeneration, control, delayed combustion, radiant flame, localized heating, freedom from ash, handling of coal and ashes, and many others may rule out the use of coal.

Under such conditions, if natural gas or fuel oil is available at a reasonable price, or if a by-product fuel such as coke-oven or blast-furnace gas can be used, one would hesitate before building an expensive gas-producer plant, with its attendant dirt, heat, and operating difficulties. If the fuel requirements do not amount to more than 1500 lb of coal per hr, a gas producer would seldom be justified; but if coal is cheap compared to other fuels, and if a gaseous fuel is needed, the use of producer gas will be worth investigation.

Table 1 may be used for a quick comparison between the costs of several fuels. It shows the price that can be paid for fuel oil or natural gas as compared to cost of coal delivered to the gas-producer plant, taking into account the cost of making the producer gas, including depreciation, and the cost of heating and atomizing the oil. The cost of gasifying 1 ton of coal or coke was estimated at $1.75; but this figure might be higher or lower, depending upon the size of the plant, wage rates, number of men required for operation, and similar factors (see Table 2). This table does not agree at all with the comparisons made in the advertising matter of many manufacturers, for the reason that they use a much lower charge for producer operation.

The choice of fuels cannot always be made strictly on a cost basis. The supply of natural gas or oil may be restricted or cut off suddenly in the coldest winter weather, while coal will probably always be available, in spite of numerous recent threats against the life of one of our greatest industries. The relative prices of fuels do not remain constant. Since 1939, the price of natural gas has stayed the same in most districts, while coal has advanced 30 to 45 per cent, and fuel oil 50 to 100 per cent. Any of these conditions may make the construction of a gas-producer plant imperative.

As can be seen from the cost of gasifying coal shown in Table 2, the item of depreciation is a very appreciable part of the cost. But once the money for a producer plant has been spent, due to emergency conditions or for other reasons, the matter of depreciation can be neglected, and natural gas or oil would have to be about 10 per cent cheaper than indicated in Table 1, in order to compete with producer gas.

TABLE 1 COMPARISON OF FUEL COSTS

Hot raw producer gas: Price of coal per ton delv'd. 27,000,000 Btu	Hot raw producer gas: Cost of producer gas per ton coal 19,200,000 Btu	Hot raw producer gas: Cost of producer gas per 1,000,000 Btu	Fuel oil: Equivalent price per gal, or 145,000 Btu	Natural gas: Equivalent price per 1000 cu ft or 1,000,000 Btu
$2.00	$3.75	$0.195	$0.0253	$0.195
2.50	4.25	0.221	0.0291	0.221
3.00	4.75	0.247	0.0328	0.247
3.50	5.25	0.273	0.0366	0.273
4.00	5.75	0.299	0.0404	0.299
4.50	6.25	0.325	0.0442	0.325
5.00	6.75	0.351	0.0480	0.351
5.50	7.25	0.377	0.0517	0.377
6.00	7.75	0.403	0.0555	0.403
6.50	8.25	0.430	0.0594	0.430
7.00	8.75	0.456	0.0632	0.456

Cost of gasifying coal per net ton is assumed to be $1.75 (see Table 2).

Cost of producer gas per million Btu is based on:	Per lb coal
60 cu ft of gas at 60 F per lb coal, and 140 Btu per cu ft	8400 Btu
Sensible heat with gas delivered to furnace at 700 F, 60 cu ft of gas at 11 Btu per cu ft	660 Btu
Tar, 60 cu ft of gas at 0.0006 lb tar per cu ft and 15,000 Btu per lb tar	540 Btu
Total	9600

Heat in producer gas at 700 F per ton coal, 2000 × 9600 or 19,200,000 Btu.

Price of fuel oil allows for charge of $0.003 per gal for steam, power, and depreciation but no charge for depreciation. If depreciation charge on gas-producer plant is neglected, deduct $0.0046 per gal from price of oil shown.

Price of natural gas covers fuel cost only. If depreciation charge on gas-producer plant is neglected, deduct $0.032 per 1000 cu ft from price of gas shown.

Selection of Producer-Gas Fuel

If the foregoing considerations seem to warrant the construction of a producer plant, the next step is to decide what fuel will be used to make the gas. There are two distinct types of producer gas—that made from bituminous coal, and that made from anthracite or coke. Since bituminous coal in most parts of the country is cheaper than anthracite or coke, it follows that gas manufactured from it will be the cheapest gas that can be made. Cost alone, however, may not be the deciding factor.

If the heat requirements of the furnaces are large, if the gas can be burned in the furnaces through a few ports instead of a

[1] Chief Engineer, Harbison-Walker Refractories Company.

Presented at a joint meeting of the American Institute of Mining and Metallurgical Engineers and The American Society of Mechanical Engineers, Pittsburgh, Pa., Oct. 28–29, 1943.

TABLE 2 GAS-PRODUCER OPERATING COSTS

	Small plant, 1 8-ft producer		Larger plant, 2 10-ft producers	
Fuel:	Per week	Per ton	Per week	Per ton
Tons of coal gasified	120	...	400	...
Tons of coal used to generate steam for blowing producers	8	...	25	...
Operating cost:				
Labor				
Gas producer and boiler operator 1 man 168 hr at $.80	$134.40	...	$134.40	...
Dust removal from dust legs				
Small plant 16 hr at $.65	10.40	...	...	...
Larger plant 32 hr at $.65	...	...	20.80	...
Coal and ash handling at $.10 per ton coal	12.00	...	40.00	...
Burning out flues, once every 6 weeks, averaging 1 man per week 8 hrs at $.65	5.20	...	5.20	...
Repair labor				
Small plant, 1 man 4 hr at $.90	3.60	...	...	...
Larger plant, 1 man 8 hr at $.90	...	...	7.20	...
Total labor	$165.60	$1.28	$207.60	$0.52
Power				
Small plant 1100 kwhr at $.012	13.20	0.11	...	...
Larger plant 2400 kwhr at $.012	...	...	28.80	.07
Repair materials, including coal machinery, producers, auxiliaries, boilers, painting, etc., estimated average during life of plant	30.00	0.25	60.00	0.15
Boiler feedwater and producer cooling water, based on recirculation of cooling water, 190 gal per ton coal at $.10 per M gal	2.28	0.02	7.60	0.02
Oil, grease, waste, supplies	3.00	0.03	6.00	0.02
Coal for steam, at $3.50 per ton	28.00	0.23	87.50	0.22
Total cost of gasifying coal, no depreciation charge		$1.92		$1.00
Depreciation, on basis of 10 per cent per year on investment of the following:				
Small plant, and gas mains $60,000	115.00	0.96	...	...
Larger plant, and gas mains 100,000	...	...	192.00	.48
Total, including depreciation		$2.88		$1.48

large number of individual burners, and if the producers can be located near the furnaces, the selection would favor hot raw gas made from bituminous coal. If less fuel is needed, or if gas must be distributed to a number of furnaces or individual burners located at some distance from the producer plant, the greater expense of using anthracite or coke might be warranted. Wherever practical, both kinds of gases are used in their hot raw state.

It seems to be a current belief that a "gas coal," with a volatile content above 35 per cent, is the best fuel for bituminous producers. It does make a rich gas, and it is usually a free-burning coal which does not cake badly in the producer. On the other hand, the gas may contain more vaporized tar which will be objectionable unless the gas can be kept hot until it reaches the furnaces. The ideal producer fuel would be a 2 or 3-in. lump coal, with fines below $^3/_4$ in. screened out, having an ash-fusion point above 2500 F, and free-burning characteristics which prevent the top of the fuel bed from becoming a sticky mass and caking. In actual practice, mine-run or slack coals are often used at some reduction in capacity, although more dust is carried over into the mains when using fine coal. A gummy condition at the top of the fuel bed can be overcome by keeping it at a higher temperature. The amount of ash in the coal does not make as much difference as its fusion point does, and even coal with low-fusion ash can be used by applying more steam in the blast.

Mine-run or slack bituminous coal can be used in producers because the coking action at the top of the fuel bed will provide passages for the gas. When anthracite or coke fuel is used, the only openings for the flow of gas through the upper part of the charge will be the spaces between the particles of fuel. Therefore most of the dust finer than $^1/_4$ or $^3/_8$ in. must be screened out. The term "coke breeze" can cover a multitude of sins and, before deciding upon this as a source of gas, it must be positively ascertained that the quoted price covers a fuel sufficiently free of fines to make it usable in a producer. Much of the finer coke is now used at the plants where it is made, in producers for underfiring the by-product ovens, and in steam boilers.

The Gas-Producer Plant

To take its rightful place among other fuels, producer gas must be made at the lowest possible cost, with the minimum amount of labor and operating difficulties. The gas producer is an important item, but it is only one part of the gas-making plant. The best producer cannot make gas without the proper operation and control, and it cannot deliver gas to the furnaces without a proper distribution system. There are few places where proper planning and anticipation of difficulties will have a greater effect on the success of the project than in the design of a producer-gas system. This is particularly true when using bituminous coal.

It is possible to lay out a plant so that one man per shift can take care of either one or two producers, a boiler, and the handling of coal and ashes. He might have to have occasional help in cleaning out dust legs, or in dumping a car of coal, but on the other hand, if the producer is located close enough to the furnace, he may also serve as the furnace operator.

Coal can be discharged from trucks or cars through a hopper, feeder, and bucket elevator to the coalbins. A double-roll crusher should be provided so that mine-run coal can be used even if it is planned to use sized coal. Bins above the producers can be large enough to carry a 2-day supply of coal, which is the preferable arrangement, or the feed bins can be smaller with an auxiliary storage silo. The equipment should be designed so that no hand labor is necessary except in occasional emergencies when coal must be reclaimed from an outdoor stock pile. Segregation of coarse and fine coal in the bins must be minimized. It should never be necessary for an operator to enter a coal-feed bin, as there is always a slight danger that gas may leak up into the bin and the man might be overcome.

The operating floor of a producer plant is really the second floor of the building, level with the top of the producers. All control instruments, motor starters, steam gages, water columns, valves, and air blowers for the producers should be located on this operating floor. The boiler stack can sometimes be combined with the burnout stack for the gas lines. Ashes from producers and boilers should be discharged to a skip hoist or conveyer which delivers them to an overhead ash bin so that no hand labor is necessary.

The lower floor of the building should be enclosed, as the producers do not supply enough heat to prevent freezing around the wet ashes, floors, and conveyers. Floors and pits should be drained so that a hose can be used for cleaning. The operating floor must be well ventilated and should have large doors which can be left open in summer and closed in cold weather. Louvers are usually used in the side walls just underneath the coalbins so that no gas can accumulate in the building. Oxygen apparatus should be available in case a man is overcome with gas, although this would never happen under normal operating conditions. Water-cooled poker tips have to be built up by welding every few weeks, and chain-hoist equipment must be provided for handling them.

Approximately 100 gal of water per ton of coal must be converted into steam for the producer blast, in addition to any heating or power load on the boilers, and 200 gal per hr is needed for cooling the poker, top, and coal feeder of each producer, regardless of capacity. If water is scarce or expensive, the cooling water can be recirculated to a tank on the upper floor of the building. Water-cooled valves in the gas mains have been experimented with but have not proved very dependable.

Bituminous-Type Gas Producer

Gas has been made for years with little improvement in the producing and control equipment, auxiliaries, and operating procedure. Stationary and revolving hand-poked producers gave way to mechanical types, but even today possibly 75 per cent of the producer systems in service have gas-making equipment which requires sledging of clinkers and much hard labor, delivering a gas which varies in heat value and temperature. The old distribution mains are even worse, requiring much labor and weekly burnouts. These things have given producer gas made from bituminous coal a poor reputation in industry, even though the facilities are now available for dependable operation.

The modern bituminous gas producer is a revolving vertical steel cylinder lined with refractory brick, with a stationary water-cooled top through which coal is fed, gas is removed, and pokers are operated. The bottom is sealed by a revolving water-sealed ash pan, which encloses the air-blast hood and plows for continuously removing the ashes. The air blast is usually furnished by a steam-driven turboblower, at a pressure of about 10 in. of water, and gas leaves the producer at a temperature of 1250 to 1500 F, and a pressure up to 1 in. of water.

The producer manufacturers have done a fine job in developing machines which will make good gas with almost no interruptions when operated in a proper manner. They claim, however, with a great deal of justification, that it is almost impossible to get the users to spend the money for the correct flue system and control equipment needed to make the operation clean, dependable, and free from hard labor. The manufacturers have developed a simple rugged machine requiring almost no repairs. They have designed a center blast hood to give proper distribution of air without the use of tuyères in the outer walls. They have removed the arms which formerly obstructed the flow of ashes, and have provided for continuous ash removal, both of which help to maintain an even fuel bed and to prevent the loss of carbon in the ash. They have equalized the flow of air through the bed of hot coke by providing a means for stopping the rotation of the ash pan automatically for a few seconds at a time, while the upper part of the producer continues to revolve. This causes a grinding action in the fuel bed which reduces blowholes and unequal flow of gas. Coal feeders now give excellent distribution and control of feeding rate without leakage of gas. The motion of the water-cooled pokers has been changed to give more frequent and thorough agitation of the upper part of the fuel bed without plastering the hot sticky ash against the walls of the producer. Both the poking and grinding actions are necessary to break up the caking of the coal in the fuel bed, and to prevent channels and blowholes which cause hot spots in the fuel bed and to permit the gas to burn to CO_2 in the producer.

Auxiliary and Control Equipment

The operation of a producer must be kept constant, in the face of continually changing demands for gas, and many variations in fuel and fire bed. This is almost impossible under strictly manual operation.

Gas is made by blowing a mixture of steam and air through a deep bed of incandescent carbon. If air alone were used, the fuel bed would become very hot, resulting in clinker trouble in the producer and a very lean gas.

The fire bed of the producer contains four zones as follows:

1 The ash bed at the bottom, which protects the blast hood from the heat and aids in distributing air from the hood to the fuel bed.

2 The oxidation zone, where the only reaction is the almost complete combustion of carbon to CO_2, with the liberation of 14,550 Btu per lb of carbon. This zone is only about 6 in. thick and is the hottest zone in the producer.

3 The reduction zone above the oxidation zone, where the CO_2 is reduced to CO by the hot carbon, with a corresponding endothermic reaction of 5850 Btu per pound of carbon, and the steam reacts with the carbon to form hydrogen, CO and CO_2, further reducing the temperature of the fuel bed.

4 The distillation zone at the top where the volatile matter in the coal is distilled off and moisture is evaporated.

The fuel requires 2 hr or more to pass through these reactions, but the air, steam, and gas are in contact with the fuel for little more than 1 sec in a bituminous producer, and for possibly 3 sec in the coke type. It is therefore exceedingly important that the various zones are held constant in thickness, "porosity," and temperature, and it is evident that this can only be done with equipment that has been carefully developed for the purpose, with controls made as automatic as possible, and with intelligent operation. When the load varies, these factors become increasingly important. Variations in fineness or caking qualities of the coal, and in the fusion point of the ash, affect the operation.

Air must be delivered to the blast hood in a manner which can be automatically controlled by the demand for gas, in spite of variations in the resistance of the fuel bed. Older producers usually were equipped with steam-jet blowers, but the need for fan-type blowers is now almost universally recognized, and many old producers have been equipped with modern blast equipment. When used on bituminous producers, the blowers are directly connected to small variable-speed steam turbines, and the exhaust steam is connected into the air blast. On coke and anthracite producers, the steam pressure from the water-jacketed shell is not high enough to operate a turbine, and the blower is therefore driven by electric power.

In most plants, particularly where the gas demand is not constant, the volume of the air blast is controlled by a pressure regulator connected to the gas main. The pressure in the main is usually between 0.2 and 1 in. of water. If the furnace operator turns on more gas, the pressure in the main immediately drops and the regulator feeds more steam to the turbine. The small pipe between the gas main and the regulator is kept free from tar and dust by blowing a very small amount of air through it into the main. Variations in resistance of the fuel bed will not affect the accuracy of the control, and the operator can adjust his regulator to allow for the pressure needed in the gas mains. When used with a motor-driven blower, the regulator adjusts a damper in the air line.

The volume of gas leaving a producer cannot be measured, due to the tar and dust, but the amount of air blown to the producer can be indicated and this is a measure of the gas delivered. All producers should be equipped with an orifice plate in the air-blast line, with an indicating or recording differential gage on the instrument panel to show the operator how much air is being fed to each producer. The operator will then know when the furnaces are using more gas, and he can regulate his coal feed and make other adjustments accordingly. He will also know whether each producer is carrying its share of the load. This indication of air volume is used on very few producers, but all operators who have tried it report that it is one of the most valuable instruments in the plant.

Where a producer plant is operating in connection with a single furnace, and both the producer and the furnace are under the control of one man, automatic regulation can be obtained by means of volume instead of pressure. The furnace operator will adjust the volume-control instrument to give enough gas for the furnace, and this instrument will then automatically control the speed of the turbine so that a constant volume of air is fed to the producer, regardless of the resistance against which this air must be delivered. This method has the advantage that the producer

will deliver the required amount of gas, regardless of obstructions in the line between the producer and the furnace.

The amount of steam in the air blast is one of the most important factors in producer operation. In the reduction zone in the producer, the CO_2 is reduced to CO by contact with hot carbon, with a consequent absorption of heat amounting to 5850 Btu per lb of carbon. The hotter the fuel bed, the more rapid and complete will be this reaction, resulting in less CO_2 and more CO in the gas produced. The high temperature also results in more active action between the carbon and the steam. However, the temperature which can be maintained is limited by the fusing temperature of the ash, so enough steam must be introduced to lower the temperature of the reduction zone to a safe point, by combining with the hot carbon to form H_2, CO, and some CO_2.

When the old steam-jet blowers were used, the proportion of steam to air could not be accurately controlled and too much steam was usually put into the producers. When a turbine- or motor-driven blower is used, the amount of steam is adjusted by observing the temperature of the mixture of air and steam. This is usually at some point between 130 and 150 F. When the correct figure has once been determined for a certain coal, it is not difficult for a producer operator to maintain this so-called "saturation temperature." The exhaust steam from the turbine is discharged into the air blast, and some live steam is usually added. When more air is needed the turbine is speeded up, automatically adding more steam to the blast. Automatic temperature control of the blast is often furnished but is not absolutely needed when turbines are used. It is necessary when blowers are motor-driven.

Fig. 1 shows the blast temperatures corresponding to various inlet-air temperatures and pounds of steam per pound of coal. Fig. 2 shows results of tests reported by W. P. Chandler of Carnegie-Illinois Steel Corporation indicating the increase in the quality of the gas when the proportion of steam in the blast was decreased. In practice, however, it is usually dollar efficiency rather than thermal efficiency which counts, and as coals with high ash-fusion temperatures are rarely available, we choose more steam and a poorer gas rather than a job of sledging clinkers out of the producers.

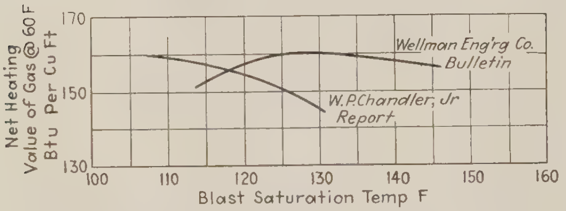

Fig. 1 Relation Between Steam Used per Pound of Coal and Blast Saturation Temperature

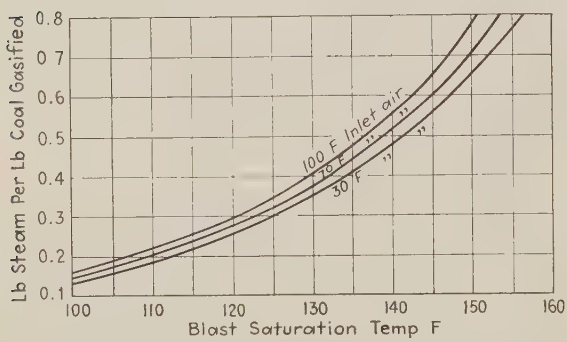

Fig. 2 Relation Between Heating Value of Gas and Blast Saturation Temperature

Producer gas is a very "lean" gas, due to the high percentage of inert nitrogen introduced with the oxygen in the blast. The use of steam as a reducing agent to lower the temperature of the fuel bed and prevent the formation of clinkers, actually enriches the gas because it adds hydrogen without increasing the amount of inert gases. However, fuel must be burned to generate the steam, and this fuel amounts to about 5 per cent of the coal gasified. Therefore, CO_2 is sometimes used in the blast, to lower the fuel-bed temperature, but this is only profitable where the CO_2 content of the gases is very high, as in the exhaust gases from lime kilns. Proper control of the percentage of CO_2 added to the blast is quite difficult.

High fuel-bed temperatures do not necessarily mean high gas temperatures leaving the producers. Gas temperatures usually run between 1250 and 1500 F, but may be as high as 1800 to 1900 F when used in kilns for burning limestone, where producers are usually located very close to the kilns.

All automatic producers have an adjustable mechanical coal feed. Practically all of these are adjusted by hand. There is a recording thermocouple in the gas stream leaving the producer, and the operator adjusts the coal feed to maintain a reasonably constant gas temperature. If more air is blown through the producer, the top of the fuel bed soon increases in temperature, and the operator feeds more coal to prevent the gas from getting too hot. If the operator is provided with an orifice meter on the air blast, he knows when more gas is being generated without waiting for the temperature to increase, and he can regulate his coal feed accordingly. Automatic regulation of coal feed is now being applied, using the temperature of the gas leaving the producer to regulate the rate of feed. This is very successful, as it re-

TABLE 3 PRODUCER-GAS DATA

Fuel used in producer	Bituminous coal	Anthracite coal	Coke breeze
Fuel gasified, lb per sq ft per hr	30–70	15–30	15–30
Volume of gas at 60 F, cu ft per lb coal	60	65	68
Temperature of gas leaving producer, deg F	1250–1500	550–650	550–650
Lower or net heating values, Btu:			
Coal or coke used, per lb	13500	12500	12000
Steam 0.4 lb per lb fuel	450	(450)	(450)
(Anthracite and coke producers make own steam)			
Heat input to producer, per lb fuel, Btu	13950	12500	12000
Raw producer gas, per cu ft at 60 F	140	130	120
Sensible heat of gas leaving producer per cu ft	23	10	10
Tar in hot gas leaving producer, 0.0006 lb tar per cu ft gas at 15,000 Btu	9	..	..
Heat output from producer, per cu ft, Btu	172	140	130
Heat output from producer, per lb fuel, Btu	10320	9100	8840
Efficiency of producer, not including losses in boiler or gas lines	73.9	72.7	73.6
Typical analysis of gas, per cent:			
CO	22.5	24.8	26.0
H_2	12.5	15.0	11.0
Hydrocarbons	3.1	0.9	0.7
CO_2	7.4	9.0	7.6
N_2	54.5	50.3	54.7
	100.0	100.0	100.0
Air for perfect combustion, cu ft per cu ft gas	1.17	1.04	0.95
Additional air for combustion of 0.0006 lb tar per cu ft of bituminous gas	0.11	...	...
	1.28		
Products of perfect combustion, cu ft per cu ft gas	2.14	1.83	1.76
Weight of producer gas, lb per cu ft	0.069	0.066	0.069
Weight of air for perfect combustion, lb per cu ft of gas	0.098	0.080	0.073
Weight of products of perfect combustion lb per cu ft of producer gas	0.167	0.146	0.142
Theoretical flame temperature, based upon gas at 60 F, deg F	3170	3150	3000

duces the work of the operator and improves the quality of the gas.

Table 3 gives general information on the different types of producer gas and is useful in the design of distribution systems, burners, and furnaces, and in the comparison of this gas with other fuel.

Distribution System for Bituminous Producer Gas

Raw gas made from bituminous coal is a hot dirty fuel to handle. It contains dust from the fine coal falling into the producer and soot from the cracking of the hydrocarbons. When using slack coal, the dust carried over into the mains may amount to 5 per cent of the weight of the coal. This will fill up a round pipe so rapidly that the flue would have to be cleaned or "burned out" once a week, shutting down the furnaces and producers during the operation.

This gas also contains tar vapors which will condense as the gas cools, gumming up valves and burners, seeping out of cleanout doors, and mixing with the dust to form a cokelike substance. It has a temperature of 1250 to 1500 F, when it leaves the producer, and therefore has nearly twice the volume of gas made from coke or anthracite and 18 times the volume of natural gas for the same Btu value. Consequently, mains and valves are large and costly. As a result, bituminous gas has been most frequently applied to large furnaces located near the producer plant and more rarely used where the gas must be distributed for greater distances and to a large number of burners.

Having outlined the causes of the difficulties encountered in the distribution of hot raw bituminous gas, the next step is to see what can be done to overcome them. In the case of old gas mains already in use, only a little improvement is possible without extensive alterations. Where a new distribution system is to be installed, it is entirely possible to increase the length of time between "burnouts" to 2 months, or even to a year, at the same time conserving the sensible heat of the gas and smoothing out the furnace operation.

Gas mains can be built without any horizontal bottom surfaces on which dust can accumulate. They can be constructed with a saw-tooth bottom, with provision for removing the dust at all of the low points. Dust will sometimes accumulate on the slopes but small openings can be provided for steam lances in the top of the pipe, so that the dust can be blown down into the pockets at the bottom. However, this is a hot and dirty job, and a better scheme is to install soot blowers at every point in the mains where dust can settle, with legs or pockets having double seals through which the dust can be removed while gas is flowing. These blowers can be standard boiler soot blowers, which will withstand the gas temperatures quite well, but are not entirely resistant to the higher burnout temperatures. On the other hand, if burnouts can be greatly reduced or eliminated by the soot blowers, the soot blowers will not be damaged by the burnouts.

The removal of the dust from the pockets is also a disagreeable job, particularly if it must be handled in wheelbarrows. This dust could be sluiced into a stream of water, but this is rarely available. A steam-ejector vacuum system is being used to remove the dust and deliver it in a dampened condition into the ash bin. This dust contains about 75 per cent carbon and 25 per cent ash and is "red hot" when removed from the mains.

To prevent trouble with the tar, the gas temperature must be kept high enough so that the vapors will not condense, or else the gas must be cooled and washed. Insulation of new gas lines is now relatively simple since insulating refractory brick can be used for the complete lining of the mains, and gas can be delivered 100 ft from the producer plant with a temperature loss of not more than 300 deg F, including dust catchers and mains. Washing of bituminous gas has been tried on numerous installations in the past, and there is at least one successful plant in operation today. However, it involves the use of expensive equipment and the loss of sensible heat amounting to 6 to 12 per cent of the total Btu content of the hot gas as well as the loss of the tar. Either the tar must be wasted, or costly recovery and handling equipment must be installed.

Producers and Distribution Systems for Anthracite and Coke Gas

Gas made from coke or anthracite, while higher in first cost, is cooler, cleaner, and easier to handle, and may be washed if necessary with less difficulty and loss of heat. It is comparatively free from dust as it leaves the producer because anthracite producers gasify only one half as much fuel as do the bituminous type, and because the fuel used contains less fines and almost no hydrocarbons, and flows directly from distributing pipes onto the top of the fuel bed instead of dropping through a stream of moving gases. It is entirely free from tar and has a temperature of about 600 F, making it possible to deliver it through steel pipe lines of smaller size, with insulation on the outside of the pipe. No time need be lost in burning out the mains. Higher pressures and velocities can be used and a booster blower can even be connected to increase the pressure of the gas after it leaves the producers. In the past this gas has usually been washed, but in recent installations the velocity has been increased by the use of bowers to the point where dust will not settle out, and gases are distributed in the hot raw condition. Standard valves, fittings, and burners can be used, and the burners require much less attention from the furnace operators.

The producers used for coke and anthracite are quite different from bituminous producers, mainly because these fuels do not contain tar and hydrocarbons. Therefore the fuel bed does not cake to any great extent and no mechanical poker is needed. The bed can be 5 ft deep instead of about 2.5 ft, resulting in cooler gas. The construction is very much simpler than in the bituminous machine, since the shell is stationary, while only the bottom revolves. The blast hood is large and is usually eccentric in shape, so that it grinds the ashes and agitates the fuel bed as it revolves. In some producers it is attached to the revolving ash pan in which case a deep water seal is used and the blast pressure is limited to approximately 20 in. of water. In others, the revolving blast hood supports the fuel bed, and ashes are discharged through the hood into a stationary hopper below. These producers can be operated with a blast pressure of several pounds, since no water seal is used. Coal feeders are either stationary or revolving. The producer shell is water-jacketed instead of being lined with brick and generates enough steam to mix with the air blast.

Refractories

The refractory-brick lining of a bituminous producer is subjected to continuous abrasion from the passage of fuel and ashes, and to occasional destruction from the formation of clinkers and the necessity of breaking them loose from the walls with heavy bars. The temperature of the lining usually is not excessive, but hot spots sometimes develop, due to channeling of the fires. A dense, strong, high-heat-duty brick is required to resist these conditions. The lining can be either $4^1/_2$ in. or 6 in. thick, backed up with $2^1/_2$ in. of strong insulation next to the shell. A high-temperature cold-setting refractory mortar should be used, and all joints should be kept as tight as possible. When using coal having a very low ash-fusion temperature a few courses of silicon-carbide brick are sometimes used at the clinker line.

Mains for carrying hot raw bituminous gas do not exceed 1400 F except during burnouts. Steam jets and lances must be used to stir up the dust. Formerly, mains were lined with $4^1/_2$ in. of

fireclay brick, sometimes surrounded with insulation. The development of lightweight refractory brick which will withstand these conditions has greatly simplified the construction of these mains. The entire 9-in. lining can be built of 2600-deg insulating refractories, or lower-temperature insulating brick can be used in the outer $4^1/_2$-in. portion. This brick is somewhat lower in cost and higher in insulating value. Flue linings usually involve a great deal of complicated brickwork and the use of insulating refractories which can be easily cut, sawed, ground, or rubbed into any desired shape greatly reduces the bricklaying labor cost. A cold-setting mortar should be used, with expansion joints about every 20 ft. No fireclay brick need be used except in the connection from the producer to the dust catcher, and for construction of the valve seats. Cast-iron seats are now seldom used.

Furnaces and Burners

Producer gas is not only a cheap fuel, but is admirably adapted to many heating operations, particularly where a soft luminous flame is desired. As can be seen from Table 3, it has a theoretical flame temperature of about 3100 F, as compared to 3700 F, for natural gas and 3800 F for oil. This makes it especially suited to steel reheating, where the entire furnace must be filled with a hazy slightly reducing flame and "hot spots" must be avoided. The same characteristics, at slightly higher temperatures, make it suitable for burning refractory brick. A glass tank can be completely filled with a luminous flame having the high radiation characteristics so desirable for heating this transparent molten bath. With producer gas, it is easy to get delayed combustion, even when using highly preheated air, an operation that is very difficult when using natural gas or oil.

Bituminous producer gas is used for firing vertical-shaft lime kilns and also rotary kilns for lime and other products where freedom from ash deposits is necessary. Freedom from ash makes it suitable for firing many ceramic products, where both bituminous and coke or anthracite gas are being used.

In many of these furnaces, the fuel requirements are large, and the gas and air are merely admitted through ports in the furnace walls. The air is usually preheated by regeneration or other means, and this preheating becomes very necessary when high temperatures must be reached. It is sometimes claimed that there is no object in keeping the gas hot between the producers and the furnaces, as this may reduce the furnace efficiency because the exhaust gases will not be cooled in the gas regenerators. Intermittent steam jets can be used if necessary in order to keep soot from building up on the reversing valves and burner ports.

Where a number of smaller burners have to be used, bituminous gas is usually fired through a cast-iron burner with a fireclay burner block. The gas flow is controlled by a slide or inverted-cone valve, which has to be opened and closed about once an hour to keep it clean. The air, preferably preheated, often acts as an injector to draw the gas into the burner block. A very short oxidizing flame can be obtained by using enough air and moving the air pipe away from the block. A reducing or delayed combustion flame is produced by using less air and moving the pipe closer to the throat of the burner. These burners must be thoroughly cleaned about once every 24 hr and large cleanout doors must be provided. Since the gas going to each burner cannot be measured, it is advisable to have an orifice and an indicating differential gage in each air line. The air can then be set for any desired quantity, and the gas adjusted to give the required temperature and flame quality.

Producer gas made from anthracite or coke, either washed or in the hot raw condition, can be burned in standard gas burners large enough to allow for the low Btu value of the gas, or it can be regenerated and burned in ports. It is particularly suited to plants where the burners are widely scattered, as in smaller heating furnaces, and in the underfiring of coke ovens.

Everything considered, producer gas made from bituminous coal, anthracite, or coke can be a very desirable fuel if proper consideration is given to the economic, engineering, and operating factors which so materially affect the success of the project.

Pulsation and Its Effect on Flowmeters[1]

By E. J. LINDAHL,[2] COLUMBUS, OHIO

Flowmeter readings are apt to be seriously in error if the fluid flowing through the meter is subjected to rapid recurring variations in velocity or pressure or both. Flow having these variations is thought of as being "pulsating flow." Much thought has been given to pulsating flow or pulsation and much has been written about it. It is the intention of this paper to bring together some of the results which have been published.

Causes and Effects of Pulsation

STEADY flow of a medium exists when the mass rate of flow through a device is constant, when the velocity, pressure, and temperature at any point remain constant, and when thermal equilibrium has been reached by the device through which the medium is flowing. In the case of unsteady flow, one or more of the conditions mentioned does not exist. Pulsating flow can exist when rapid velocity or pressure variations occur and is seen to be a special case of unsteady flow.

The causes of pulsation are numerous. One of the chief sources of pulsation in gas pipe lines is the reciprocating compressor. Another source is water surging back and forth in a low portion of a pipe line. Air enters the intake manifold of an internal-combustion engine having pulsation due to the pumping action of the engine pistons. Clattering check valves and undamped diaphragm regulators in a line are also offenders. Steam flowing to a reciprocating engine has pulsating flow. Any device that causes intermittent flows or pressures is a source of pulsation, since pulsations take place as a result of recurring rapid variations in either velocity or pressure.

One device which is greatly affected by pulsation and which concerns engineers is the inferential meter. While it is true that there are some pulsations which have no effect on the meter reading, there are other pulsations which render the meter reading invalid. Since the measurements which involve large quantities are made with flowmeters, it is extremely important from a dollars and cents standpoint that these meters read accurately. As a result, a great deal of time and money have been spent by concerns in the gas industry to determine means for reducing the errors in meter readings resulting from pulsation. This paper will deal chiefly with the effect of pulsation on meters. In passing, it might be said that at the present time very little study has been made to determine errors in the measurement of liquids having pulsating flow.

It is now generally accepted that any inferential-head meter will measure correctly if the secondary device will measure accurately the differential pressure across the primary element, and if the average of the square roots of the instantaneous readings can be determined. In the case of steady flow these operations are comparatively simple, but when the flow is at all unsteady this is not true.

If the differential is irregular as a result of rapid variations in velocity or pressure the meter is inaccurate because of the fact that most secondary devices are too sluggish to follow the actual changes in differential pressure caused by rapidly changing flow. Furthermore, the differential pressure, indicated by the secondary device, is an approximate average of the maximum and minimum differential pressures. When the square root of this average is taken, the resulting value is higher than the average of the square roots of the instantaneous differentials, and the flow as determined from the meter will be too high.

This can be illustrated by assuming that the flow through a meter varies in a manner such that the differential is, for example, 49 in. during one second and 25 in. the next second. The average rate of flow over this period is proportional to $\frac{(49)^{1/2} + (25)^{1/2}}{2}$ or 6; if the average meter differential is 37, the rate of flow as registered by the meter is proportional to $(37)^{1/2}$ or 6.083. The error due to pulsation is $(6.083 - 6.000)/6.000$ or 1.4 per cent.

According to most investigators the error is always positive, but cases of negative error have been found which have been attributed by some engineers to pulsation. The magnitude of the error may be up in the hundreds of per cent.

Mathematical Analysis of Pulsation Error

In order to show how pulsation acts to give erroneous meter readings a mathematical analysis of three types of waves will be made. It must be kept in mind that the method of calculating the error due to pulsation is only theoretical and no attempt should be made to apply it in a practical case. It will, however, indicate why pulsation error exists.

Three wave forms, i.e., the rectangular, the sine, and the triangular, will be analyzed. Two assumptions in regard to meter behavior are made in these analyses: (*a*) it is assumed that the pulsations occur with such rapidity that the portion of the meter upon which the differential is impressed cannot follow the rapidly fluctuating differential pressures; and (*b*) it is assumed that the wave is symmetrical and that the meter gives a reading which is the mean between the upper and lower limits of the pulsation wave.

The sine wave would result if a single-cylinder compressor had the connecting rod replaced by a Scotch yoke, as shown in Fig. 1(*a*), since the piston would have simple harmonic motion and the wave displacement assumed to follow the motion of the piston. The wave would then be as shown in Fig. 1(*b*), with p as the maximum displacement of the pulsation wave and with the angular displacement of the crankpin through one revolution plotted as the abscissa.

The rectangular wave form will be first discussed in detail, since its analysis presents less of a problem than the other two.

The differentials encountered are illustrated in Fig. 2(*a*) and apply to one revolution of the crank of a compressor. The phase angle of the crank is plotted as the abscissa and the instantaneous differential as the ordinate. The meter reading (indicated by h) is taken halfway between the maximum differential $(h + p)$ due to the pulsation and $(h - p)$ the minimum differential, p being the distance between the instantaneous differential and the meter reading. The instantaneous value of the true differential is indicated by H. If K is used to designate all of the constants, such as $(2g)^{1/2}$, velocity of approach factor, etc., then Q_m, the flow as indicated by the meter, is equal to $Kh^{1/2}$. If, instead of

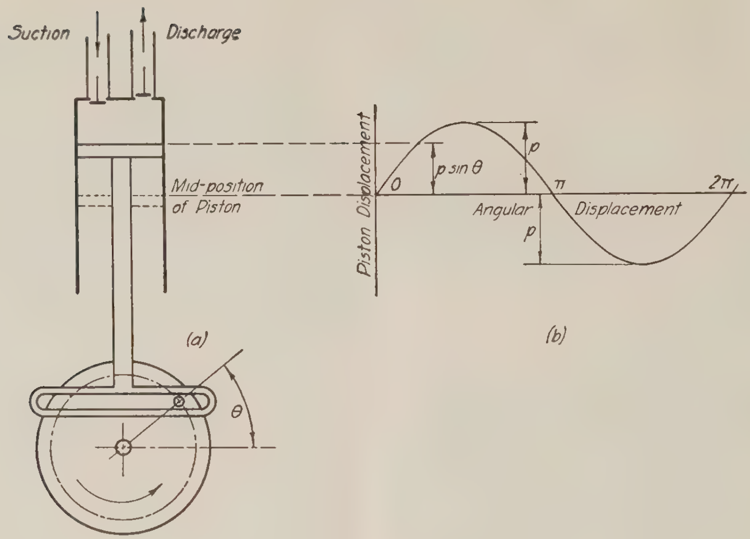

Fig. 1 Generation of Pulsation Wave

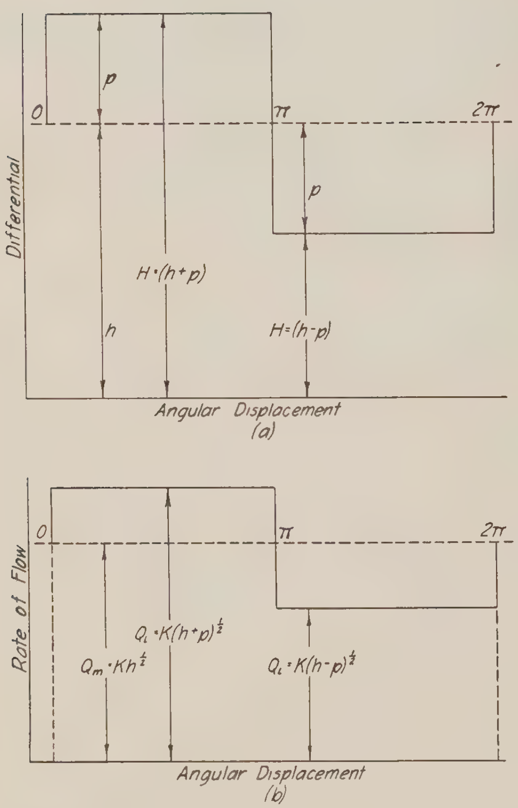

Fig. 2 Rectangular Wave

plotting the instantaneous differential, the instantaneous flow is plotted, the result is as shown in Fig. 2(*b*). If the area under the curve is taken for one cycle (angular displacement 0 to 2π), and the area is divided by the length of the cycle, there results the average ordinate which is the average rate of flow and

$$Q_a = \frac{K\,(h+p)^{1/2}\,\pi + K\,(h-p)^{1/2}\,\pi}{2\pi}$$

or

$$Q_a = \frac{K}{2}\,[(h+p)^{1/2} + (h-p)^{1/2}]$$

Then the ratio of the flow as determined by the meter to the actual rate of flow is

$$\frac{Q_m}{Q_a} = \frac{Kh^{1/2}}{\frac{K}{2}\,[(h+p)^{1/2} + (h-p)^{1/2}]}$$

or

$$\frac{Q_m}{Q_a} = \frac{2h^{1/2}}{(h+p)^{1/2} + (h-p)^{1/2}}$$

Sine Wave. As has been pointed out, a sine wave as shown in Fig. 3(*a*) will result theoretically if the connecting rod of a single-cylinder compressor is replaced by a Scotch yoke. Any distance H from the datum to the wave represents an instantaneous value of the true differential which for this particular wave form is $(h + p \sin \theta)$, while the distance h to the horizontal dashed line represents the differential as indicated by the meter. If K is again assumed to be the meter constant, the rate of flow as indicated by the meter is again $Q_m = Kh^{1/2}$, and the instantaneous true rate of flow is

$$Q_i = K(H)^{1/2} \text{ or } Q_i = K\,(h + p \sin \theta)^{1/2}$$

If the instantaneous true rates of flow are plotted the result is Fig. 3(*b*). In order to obtain the true average rate of flow it will again be necessary to determine the area under one cycle of the curve and divide this area by the length of one cycle. The flow which takes place while the crank turns through the angle $d\theta$ is

$$K\,(h + p \sin \theta)^{1/2}\,d\theta$$

and the total flow from one revolution of the crank is

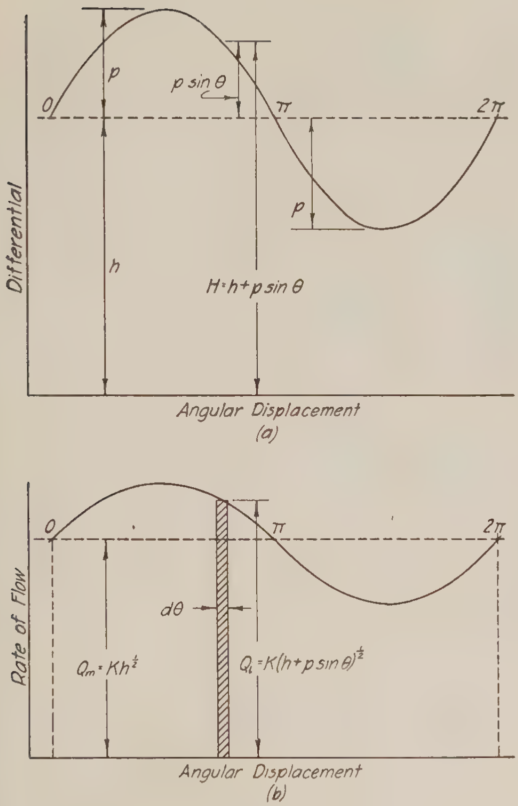

FIG. 3 SINE WAVE

$$K\int_0^{2\pi} (h + p \sin \theta)^{1/2}\, d\theta$$

The average flow over this cycle then is

$$Q_a = \frac{K}{2\pi}\int_0^{2\pi} (h + p \sin \theta)^{1/2}\, d\theta$$

If it is desired to find the actual discharge for pulsating flow from the foregoing equation, the equation must, of course, be integrated. This is done after the portion $(h + p \sin \theta)^{1/2}$ has been expanded by the binomial theorem. The binomial theorem in terms of symbols for five terms is

$$(a + b)^n = a^n + na^{n-1}b + \frac{n(n-1)}{2!}a^{n-2}b^2 + \frac{n(n-1)(n-2)}{3!}a^{n-3}b^3 + \frac{n(n-1)\,(n-2)\,(n-3)}{4!}a^{n-4}b^4$$

Then

$$(h + p \sin \theta)^{1/2} = h^{1/2} + \frac{p \sin \theta}{2h^{1/2}} - \frac{1}{8h^{3/2}}p^2 \sin^2 \theta + \frac{3}{48h^{5/2}}p^3 \sin^3 \theta - \frac{15}{384h^{7/2}}p^4 \sin^4 \theta = h^{1/2}\left[1 + \frac{p \sin \theta}{2h} - \frac{p^2 \sin^2 \theta}{8h^2} + \frac{p^3 \sin^3 \theta}{16h^3} - \frac{15\, p^4 \sin^4 \theta}{384h^4}\right]$$

and

$$Q_a = \frac{Kh^{1/2}}{2\pi}\int_0^{2\pi}\left[1 + \frac{p \sin \theta}{2h} - \frac{p^2 \sin^2 \theta}{8h^2} + \frac{p^3 \sin^3 \theta}{16h^3} - \frac{15\, p^4 \sin^4 \theta}{384h^4}\right] d\theta$$

or

$$Q_a = \frac{Kh^{1/2}}{2\pi}\left[\int_0^{2\pi} d\theta + \frac{p}{2h}\int_0^{2\pi} \sin \theta d\theta - \frac{p^2}{8h^2}\int_0^{2\pi} \sin^2 \theta d\theta + \frac{p^3}{16h^3}\int_0^{2\pi} \sin^3 \theta d\theta - \frac{15}{384}\frac{p^4}{h^4}\int_0^{2\pi} \sin^4 \theta d\theta\right]$$

Since

$$\int d\theta = \theta + c$$

$$\int \sin \theta\, d\theta = -\cos \theta + c$$

$$\int \sin^2 \theta\, d\theta = -\frac{1}{2}\cos \theta \sin \theta + \frac{1}{2}\theta + c$$

$$\int \sin^3 \theta\, d\theta = -\frac{1}{3}\cos \theta \sin^2 \theta - \frac{2}{3}\cos \theta + c$$

and

$$\int \sin^4 \theta d\theta = \frac{-\sin^3 \theta \cos \theta}{4} + \frac{3}{4}\left(-\frac{1}{2}\cos \theta \sin \theta + \frac{1}{2}\theta\right) + c$$

then the expression for discharge, when integrated is

$$Q_a = \frac{Kh^{1/2}}{2\pi}\left\{\theta - \frac{p}{2h}\cos \theta - \frac{p^2}{8h^2}\left[-\frac{1}{2}\cos \theta \sin \theta + \frac{1}{2}\theta\right] + \frac{p^3}{16h^3}\left[\frac{1}{3}\cos \theta \sin^2 \theta - \frac{2}{3}\cos \theta\right] - \frac{15}{384}\frac{p^4}{h^4}\left[-\frac{\sin^3 \theta \cos \theta}{4} + \frac{3}{4}\left(-\frac{1}{2}\cos \theta \sin \theta + \frac{1}{2}\right)\right]\right\}_0^{2\pi}$$

Since $\sin 2\pi = 0$, $\sin 0 = 0$, $\cos 2\pi = 1$, and $\cos 0 = 1$ when the limits have been substituted in the foregoing equation, the result is

$$Q_a = \frac{Kh^{1/2}}{2\pi}\left\{\left[2\pi\right] - \left[\frac{p}{2h}\right] - \left[\frac{p^2}{8h^2}\pi\right] + \left[\frac{p^3}{16h^3} \times \frac{-2}{3}\right] - \left[\frac{15}{384}\frac{p^4}{h^4} \times \frac{3}{4}\pi\right] - \left[\left(\frac{-p}{2h}\right) - \left(\frac{p^3}{16h^3} \times \frac{2}{3}\right)\right]\right\}$$

and

$$Q_a = \frac{Kh^{1/2}}{2\pi}\left[1 - \frac{p^2\pi}{8h^2} - \frac{15p^4\pi}{512h^4}\right]$$

or

$$Q_a = Kh^{1/2}\left[1 - \frac{p^2}{16h^2} - \frac{15}{1024}\frac{p^4}{h^4}\right]$$

Then the ratio of the rate of flow as indicated by the meter to the actual rate of flow when the pulsation is in the form of a sine wave, is

$$\frac{Q_m}{Q_a} = \frac{Kh^{1/2}}{Kh^{1/2}\left[1 - \dfrac{p^2}{16h^2} - \dfrac{15}{1024}\dfrac{p^4}{h^4}\right]}$$

or

$$\frac{Q_m}{Q_a} = \frac{1}{1 - \dfrac{p^2}{16h^2} - \dfrac{15}{1024}\dfrac{p^4}{h^4}}$$

It will be observed that if the amplitude of the pulsation p is zero, the flow as indicated by the meter is equal to the true rate of flow. If the meter differential and the amplitude of the pulsation are known the ratio of the two can be found and the percentage of error in the meter reading determined from the expression $\dfrac{Q_m - Q_a}{Q_a}$ which is equal to $\dfrac{Q_m}{Q_a} - 1$.

Triangular Wave Form. To take another hypothetical case, assume the wave form to be triangular as shown in Fig. 4(a). The reading of the meter is, as before, $K(h)^{1/2}$. The value of the instantaneous differential H in each case is as follows

$$\text{From } 0 \text{ to } \frac{\pi}{2}: \quad H = h + \frac{2p\theta}{\pi}$$

$$\frac{\pi}{2} \text{ to } \frac{3}{2}\pi: \quad H = h + 2p\left(1 - \frac{\theta}{\pi}\right)$$

$$\frac{3}{2}\pi \text{ to } 2\pi: \quad H = h - 2p\left(2 - \frac{\theta}{\pi}\right)$$

When the instantaneous rate of flow is plotted the curve takes the form as indicated in Fig. 4(b) and the rate of flow is as noted in the figure.

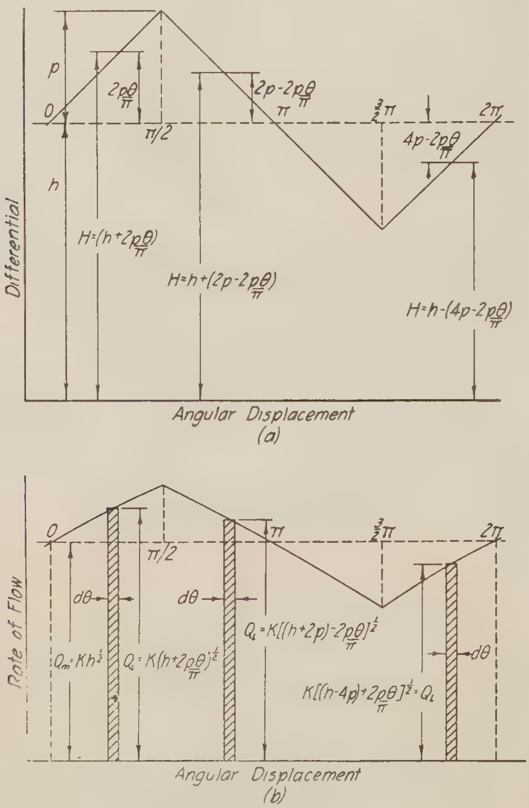

Fig. 4 Triangular Wave

The flow during the period that the crank turns through a complete revolution is

$$Q_a = \frac{K}{2\pi}\left\{\int_0^{\frac{\pi}{2}}\left[h + \frac{2p\theta}{\pi}\right]^{1/2} d\theta + \int_{\frac{\pi}{2}}^{\frac{3\pi}{2}}\left[(h + 2p) - \frac{2p\theta}{\pi}\right]^{1/2} d\theta + \int_{\frac{3\pi}{2}}^{2\pi}\left[(h - 4p) + \frac{2p\theta}{\pi}\right]^{1/2} d\theta\right\}$$

This equation is of the form $(a + bu)^n du$ which when integrated is $\dfrac{(a + bu)^{n+1}}{b(n + 1)}$. Since in this case $n = 1/2$ the form when integrated is $\dfrac{(a + bu)^{3/2}}{3/2\, b}$.

Then

$$Q_a = \frac{K}{2\pi}\left\{\left[\frac{\left(h + \frac{2p\theta}{\pi}\right)^{3/2}}{3/2 \times \frac{2p}{\pi}}\right]_0^{\frac{\pi}{2}} + \left[\frac{\left(h + 2p - \frac{2p\theta}{\pi}\right)^{3/2}}{-3/2 \times \frac{2p}{\pi}}\right]_{\frac{\pi}{2}}^{\frac{3}{2}\pi} + \left[\frac{\left(h - 4p + \frac{2p\theta}{\pi}\right)^{3/2}}{3/2 \times \frac{2p}{\pi}}\right]_{\frac{3}{2}\pi}^{2\pi}\right\}$$

and

$$Q_a = \frac{K}{2\pi}\left\{\left[\frac{(h + p)^{3/2} - h^{3/2}}{\frac{3p}{\pi}}\right] - \left[\frac{(h - p)^{3/2} - (h + p)^{3/2}}{\frac{3p}{\pi}}\right] + \left[\frac{h^{3/2} - (h - p)^{3/2}}{\frac{3p}{\pi}}\right]\right\}$$

and finally

$$Q_a = \frac{K}{3p}\left[(h + p)^{3/2} - (h - p)^{3/2}\right]$$

Then

$$\frac{Q_m}{Q_a} = \frac{Kh^{1/2}}{\dfrac{K}{3p}\left[(h + p)^{3/2} - (h - p)^{3/2}\right]}$$

or

$$\frac{Q_m}{Q_a} = \frac{3ph^{1/2}}{(h + p)^{3/2} - (h - p)^{3/2}}$$

The Theory of Pulsation

Numerous articles dealing with pulsation and the effects of pulsating flow have appeared in technical literature from time to time. Most of them deal with the inaccuracy of meters handling fluids subject to pulsation.

Among the first references is one by William Mayo Venable (1)[3] in 1905, which stated that piezometer tubes used in measuring the static head on centrifugal pumps gave values that were abnormally high. He attributed the error to pulsation caused by the limited number of vanes or blades in the pump runner.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

In the 1914–1915 Proceedings of The Institution of Civil Engineers Prof. A. H. Gibson (2) pointed out that "most devices for measuring fluid motion do not record the true mean of a pulsating flow and that the error increases," and that "fluctuations in velocity (are) accompanied by fluctuations in pressure."

In 1916 three interesting and significant articles appeared pointing out the inaccuracy of meters when measuring fluids having pulsating flow. One by Allen Hazen (3) indicated that wide and sudden variations in flow cause errors in the head produced by a Venturi meter and that elastic pipe and too-small air chambers when used with reciprocating pumps cause these errors. Another by E. G. Bailey (4) stated that steam flowing to a reciprocating engine is erroneously measured by a flowmeter because of velocity and pressure variations. F. P. Fisher (5) attributed to pulsation the discrepancy in meter readings when the meters were placed some distance apart in a pipe line from a compressor.

In 1922 the results of an investigation by Judd and Pheley (6) appeared in a bulletin published by The Ohio State University Experiment Station. This was the first real attempt to determine the nature of pulsation and to study methods of eliminating pulsation itself and the detrimental effects of pulsation. The conclusions drawn by Judd and Pheley are still considered sound; in fact, most of the later theorizing and investigating has been based upon the ideas originally brought out by them. Subsequent investigations have served to substantiate their conclusions.

Their studies were made with air on Venturi meters, orifices, nozzles, and Pitot tubes. Among the pertinent conclusions which these two men drew up are the following:

(*a*) Pulsations in pipe lines consist of sudden changes in velocity and pressure of the fluid.

(*b*) Pressure changes cause the largest pulsations.

(*c*) The pressure change is in the form of a wave front resembling a traveling sound wave of low velocity.

(*d*) The pressure wave travels with the velocity of sound.

(*e*) Velocity of pulsation is independent of the velocity of fluid flowing.

(*f*) The effect of pulsation on a flowmeter is to increase the reading. The magnitude of the error is a function of frequency and pulsation, static pressure of the fluid, type of meter, and adjacent fixture in the pipe line.

(*g*) Pulsation must be eliminated or reduced greatly to have the meter read without appreciable error.

It was also pointed out by them and now generally believed that no correction factors can be applied to a meter reading to correct for the error caused by pulsation. In most of the correction equations several things, such as frequency of pulsation, the shape of the wave, the amplitude of the wave, etc., must be taken into account. It is also felt that errors due to rapid pressure change are far more severe than changes in velocity. The fact is that there can be errors caused by rapid pressure changes without the presence of changes in the rate of flow of the mass in the pipe line. This has been illustrated by placing a positive-displacement meter on a dead-ended line. The meter valves will clatter and the meter will register a flow if pulsation is present. Likewise, a reading will be indicated on a manometer across an inferential meter, such as an orifice, when placed in a dead-ended line if pulsation exists.

Studies which have been made indicate that in addition to the primary pressure waves in the fluid between the disturbance and the primary element, there are also pressure waves of different amplitude existing in the primary element on the side opposite from the disturbance; and suggest that these waves might be slightly out of time with the waves on the other side, so that the effect of pressure variation is multiplied at times. Then, in addition to the primary waves, there are harmonics which are affected by the size and shape of the conduit on both sides of the primary element. The differential across the primary element where pulsation exists is thus a complicated varying pressure made up of many elements. This was shown by an electrical instrument developed by S. R. Beitler (7) in connection with the pulsation research sponsored by the American Gas Association and The American Society of Mechanical Engineers.

With the equipment as originally used it was possible to obtain a record of the pressure variations on either side of the primary element. However, a study of these records (along the line of reasoning mentioned) indicated that a knowledge of the differential pressure was desirable, and a special mixing switch was designed which made it possible to secure a record not only of the inlet or outlet pulsation waves but the differential pulsation waves as well. Fig. 5 shows some of the records taken with this instrument under various conditions of pulsation.

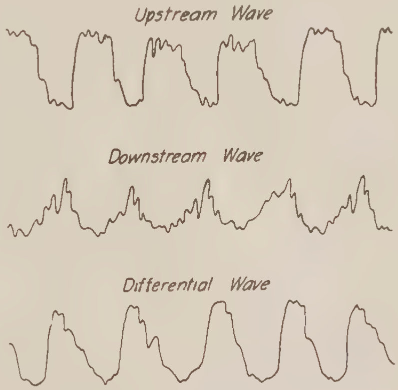

Fig. 5 Actual Pulsation Waves

A study of these records will show that there is no regularity of pulsation waves, and no apparent relation between the shape and amplitude of the waves on the two sides of the primary element, and that the differential wave bears no similarity to the other waves. These records were made at a gas-compressor station where the pulsation was produced by one compressor running at almost constant speed. The meter was placed directly on the outlet of the aftercooler so that the pulsations would be as nearly constant as possible. Because of the fact that the waves were so irregular it is practically impossible to include the effect of wave form in an equation for correcting the rate of flow.

If the pressure differential could be measured instantaneously, and if the square roots of these two pressures could be averaged, it is possible that a meter would indicate the rate of flow accurately. This would be true, because while the velocity through the primary element does not vary directly with changes in pressure waves, the energy present due to these waves will be used either in accelerating or decelerating the fluid passing through the primary element, so that the decelerations should balance the accelerations. The average flow will be indicated by the average of the square roots of the instantaneous differential pressures across the primary element.

While it is true that each meter installation presents its own problems and that each disturbance creates pulsations which cannot be analyzed, certain general conclusions in regard to pulsation can be drawn. In a paper by S. R. Beitler (8) which reports the results of research conducted at several stations, it is pointed out (*a*) that for a single diameter ratio the error becomes larger for decreasing values of the differential; (*b*) that

with a constant differential the error becomes larger with smaller diameter ratios; and (c) that at any one rate of flow the suction pulsation causes a smaller error than the discharge pulsation; but suction pulsation is just as serious as discharge pulsation if the amplitude of the pulsation is the same in both cases. These conclusions have been substantiated by other tests. Figs. 6 and 7 show the results of tests reported in this paper.

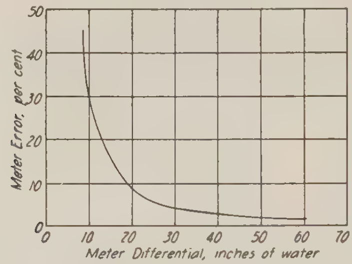

Fig. 6 Differential Vs. Error for One Diameter Ratio

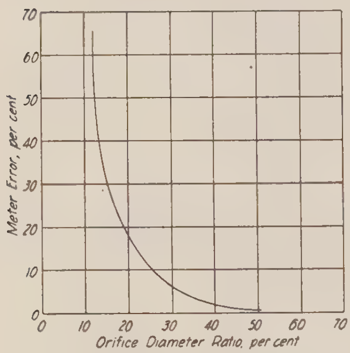

Fig. 7 Diameter Ratio Vs. Error for a Given Differential

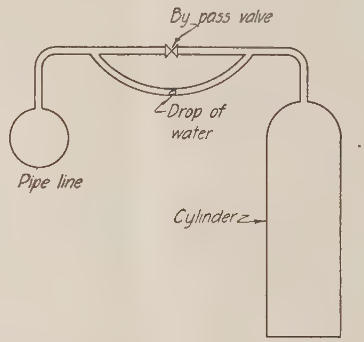

Fig. 8 Pulsation Detector (Bean)

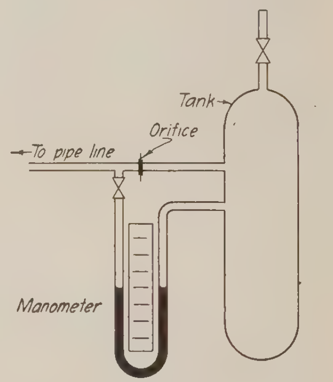

Fig. 9 Pulsation Detector (Beitler and Overbeck)

The magnitude of the error depends upon the quantity of fluid being measured, the resistance and capacity between the disturbance and the meter, and the viscosity and density of the fluid being measured.

According to H. F. Hagen (15) tests on centrifugal- and propeller-type fans are apt to be in error because of erroneous velocity and pressure readings caused by pulsating flow.

Tests (10) that have been conducted reveal that the meters made by several manufacturers gave the same amount of error when tested simultaneously.

Methods of Detecting Pulsation

If two meters are placed in series in a given line at some considerable distance apart and if the one nearer the potential source of pulsation gives a reading which differs from the reading given by the other by an amount greater than the usual discrepancy between meters, then it is certain pulsation has been created.

If a meter is subjected to constant quantity of flow and if the indicator on the meter produces a line which indicates a variable rate of flow by a wavy line, then the presence of pulsation can be suspected. This does not mean, however, that pulsation must exist if the meter charts have wavy lines nor does it mean that every case of pulsating flow will produce a wavy line.

One pulsation detector was devised by H. S. Bean (9) which had only the defect that it was too sensitive for most installations. In other words, it might indicate severe pulsations while the pulsations might be so slight that the meter error would be negligible. A sketch of Mr. Bean's detector is shown in Fig. 8. The by-pass valve is left open until the pressure in the tank reaches main pressure. The by-pass is then closed, and if the drop of water moves back and forth pulsation is present. Any slight change in static pressure or a pulsation of appreciable magnitude causes the water to be withdrawn into either the gas main or the pressure tank. If the drop of water does not move the flow is certain to be pulsationless.

A device designed by S. R. Beitler (7) and J. E. Overbeck is similar to the one just described and is shown in Fig. 9. In this device the gas-pressure tank is connected to the meter-run line through a $^1/_2$-in. line in which is placed an orifice plate, the diameter of the orifice being $^1/_8$ in. The manometer shown in the figure is then piped up to measure the pressure drop across the $^1/_8$-in. orifice. As has been pointed out previously, an orifice subject to pulsations will show a differential pressure even when there is no flow. This device takes advantage of this fact, and a differential reading on the manometer is an indication of the presence of pulsations. This device partially overcomes the defect of Mr. Bean's pulsation detector in that the liquid does not escape so readily but large rapid changes in static pressure will force the liquid out of the manometer. Slight changes of static pressure will cause differentials on the manometer which are not caused by pulsations. As in the case of Mr. Bean's detector, if no differential is shown on the manometer then it is certain that no pulsation exists.

Another instrument, which was electrical and also devised by Professor Beitler, consisted of two diaphragms of stainless steel about 1 in. diam and $^1/_{32}$ in. thick which were connected to each side of the primary metering element by very short connections and so constituted that a pressure variation would be indicated by a very slight movement of the diaphragms. Piezoelectric crystals were used to indicate the motion of the diaphragms, and the voltage produced was amplified and recorded on a recording voltmeter. The whole apparatus gave a record of the wave form at both the inlet and outlet pressure taps. The recorder was capable of responding to very rapid fluctuations of the pressure, and the complete record of the form and amplitude of the pressure variations was made on a high-speed chart. The wave forms shown in Fig. 5 were recorded by this instrument. If no pulsation is present a straight line is drawn. The entire apparatus was constructed of standard types of instruments manufactured by Brush Development Corporation, Cleveland, O.

Another instrument described by T. K. M. Smith and R. E. Morter (10), which was used for detecting pulsation, was made up of a sylphon bellows to which a pen was attached. When pulsation causes the bellows to move the pen makes a mark on a strip chart driven by a spring motor. The record of the variations of pressure is thus made on the chart.

Elimination of Pulsation

Although it is now generally felt that no equation can be written for the error caused by pulsation and no meter can be built that will measure correctly if pulsation exists, many such equations and meters have been devised.

It was pointed out by Judd and Pheley (6) and since found true by others that: (*a*) it is not feasible to apply a correction factor to a meter since the correction factor would probably change with every installation and every condition of flow; (*b*) the laws of pulsating flow are not well enough known to set up an equation for a correction factor; and (*c*) each installation presents different problems. Most of the writers who have developed equations for correction factors have failed to take into account the complexity of the pulsation wave and have treated it as a simple one. Some of those who have devised meters which correct for pulsation have failed to take into account one very important fundamental, namely, that pulsation is the result of pressure variations as well as velocity variations.

Literature which deals with many of these equations and meters will be referred to.

J. L. Hodgson (11) presents the description of a device for metering air with pulsating flow. A vane which oscillates with the pulsations carries a pointer through a hairspring. The pointer indicates the mean of pulsations. The rapid motion of the pointer is damped by vanes in an oil bath. He gives an equation for calculating a coefficient to be used with the reading obtained with the damped reading to obtain the true rate of flow. Mr. Hodgson also has another paper dealing with the subject (12).

Prof. N. P. Bailey (13) discusses a patented device which he indicates will give true-flow air under pulsating conditions. The flow of water through a calibrated orifice is claimed to be proportional to the square root of the air velocity head. Professor Bailey also has discussed similar meters in other papers (14). C. A. Dawley has patented two meters which are claimed to read correctly even if the flow is pulsating; one was patented in 1927 and the other in 1928.

H. F. Hagen (15) describes an instrument he has developed for determining the shape of the pulsation wave created by a high-speed fan.

Equations for determining the error due to pulsation or for the calculation of correction factors to be applied to the flow equation for pulsationless flow have been prepared by N. P. Bailey (14), J. L. Hodgson (12), D. Gilmour (16), and A. H. Gibson (2).

It was thought for a time that the effect of pulsation could be eliminated in a meter by placing obstructions or throttles in the gage lines. In 1922 it was pointed out by H. P. Westcott (17) that this would have no beneficial effect. Tests conducted by Eagle and Daberko (18) at The Ohio State University in 1937 showed that such devices increased the error rather than reduced it.

As far as is known now, the only way to remove every trace of error due to pulsation is to eliminate the pulsation itself. There can, however, be a slight amount of pulsation present which will not seriously affect the meter readings.

Judd and Pheley (6), as a result of their work, set down some conclusions in regard to the practical elimination of pulsation which have since been substantiated. Among them are the following:

(*a*) Because of high velocity of pulsation an excessive length of pipe line would be necessary to destroy pulsation.

(*b*) Throttling is effective, but a great deal of throttling is required to reduce pulsation error.

(*c*) Abrupt volume enlargements in the pipe line will eliminate the error if of sufficient capacity.

(*d*) For the same capacity a volume with a large diameter is better than one of equal volume and smaller diameter.

(*e*) Combination of throttling with a volume forming a muffler device is probably best for mechanically removing pulsations.

(*f*) Revolving baffles are partially successful in removing pulsation.

(*g*) The effectiveness of any quieting device depends upon its ability to dissipate or change the energy of pulsation.

One sure way to reduce pulsation to a negligible quantity is to have sufficient pressure drop between the disturbance and the meter. This can be accomplished by an orifice or a partially closed valve. In tests that have been conducted the pulsation error on the downstream side was insignificant when the pressure drop through the restriction equaled or approached the critical. This, however, in the case of a compressor, is a costly method since the purpose of the compressor will partially be defeated.

A meter placed at a considerable distance from a disturbance will not be subjected to the same degree of error as a meter placed near the disturbance. Edward Sackett (19) points out that in one instance a meter placed 6 miles from a compressor had no error. E. P. Fischer (5) noted that a meter 17 miles from a compressor had no error while one near the compressor gave considerable error. Just how far pulsation will be carried in a transmission line depends upon a number of factors and will probably be different for every installation.

Volumes placed in a line have proved quite effective in reducing pulsation to the point where meter error is no longer appreciable. The fluid having pulsation is discharged into a tank having considerable volume from whence it flows on into the line again. Several modifications of this principle have been used with success. Smith and Morter (10) discuss the use of volume tanks. They also suggest that a tank have a volume of 100 cu ft per million cu ft of gas per 24 hr reduced to actual volume under the existing pressure and that the length of the cylindrical portion of the tank be 1.75 times its diameter. One tank of their design is shown diagrammatically in Fig. 10. The pressure drop through these tanks is very low.

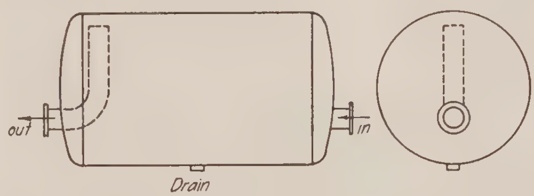

Fig. 10 Pulsation Eliminator Tank (From Smith and Morter)

Tests of volumes were conducted by Eagle and Daberko (18) in which they used the volumes in two different ways. The arrangement of the piping to the tank is shown diagrammatically in Fig. 11. The pulsation was produced by a two-stage compressor having a capacity of 350 cfm. In one series of tests they passed the air from the compressor directly through the tank by closing valve A and opening valve B (Fig. 11), valve C also being open; and in another series of tests they arranged the tank for "breathing" in the manner of a surge tank by opening valve A and closing valve B with the valve C being again open. It was found that the former method (passing the pulsating air directly through the tank) was far more effective in removing the pulsa-

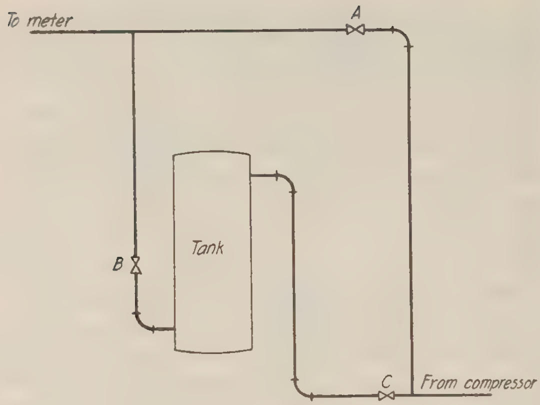

Fig. 11 Ohio State Test Tank Arrangement

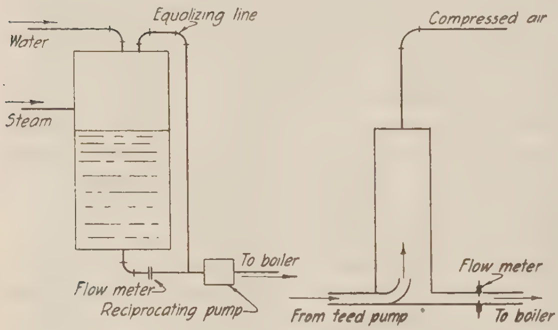

Fig. 12 Pulsation Reducers (Melas)

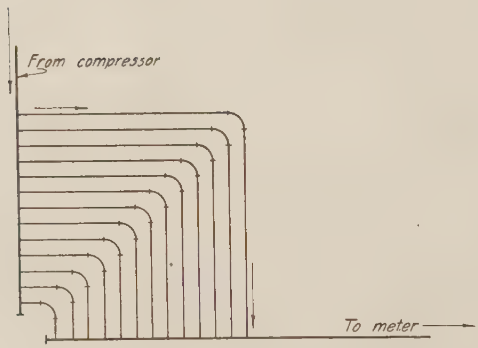

Fig. 13 Piping for Pulsation Reduction (Fischer)

tion than the latter. The tank used in these tests had a volume of 54 cu ft.

They also conducted tests when the air was passed directly through a tank having a volume of only 3 cu ft. They found that the smaller volume was about as effective in removing pulsation as the larger one. They then used the small volume lined with sound-absorbing material and placed baffles of the same material across the path of the air flow. They found that the acoustic material aided in removing pulsation to a small extent but that the acoustic material was destroyed under the action of the pulsation. They also found that the pressure drop through

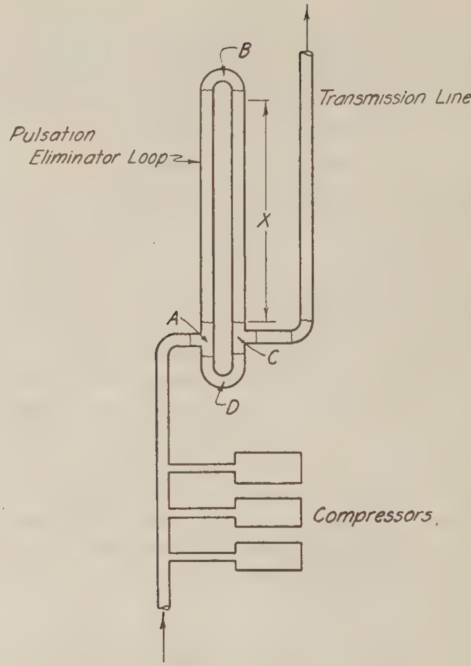

Fig. 14 Pulsation Eliminator Loop

the acoustical device was slight and concluded that the benefit was due to the sound-absorbing qualities of the device.

Two devices using the surge-tank principle are described by William Melas (20, 21, 22, 23) and shown in Fig. 12. It should be pointed out that these four articles are practically the same. Mr. Melas has used these devices in connection with a meter measuring the flow to a boiler feed pump.

F. P. Fischer (5) constructed a device (Fig. 13) which consisted of piping so arranged that various portions of the fluid under pulsating flow would have paths of different length so that the pulsation waves would interfere with one another as they joined the main pipe. Theory indicated that the waves would be broken up by this method. Elimination of the pulsation proved to be only partially accomplished.

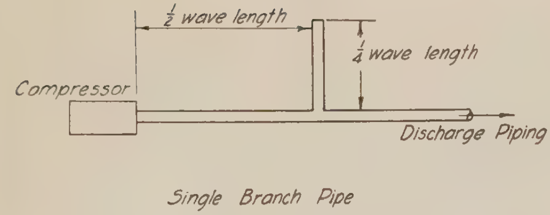
In a report written by William Mosteller to J. T. Cortelyou, both of the Southern California Gas Company, Mr. Mosteller includes a discussion of the pulsation eliminator shown in Fig. 14. He points out that for maximum effectiveness in pulsation elimination, the length of the path ABC should equal the path ADC plus one half the length of the pulsation wave. Mr. Mosteller also gives an equation for calculating the wave length and the length X in the loop.

Tests made on a pipe line from a compressor before and after the installation of this type of loop indicated that the pulsation downstream from the eliminator was less severe after the eliminator had been installed. The pulsation in the line between the eliminator and the compressor was more severe in some sections of the line and reduced in other sections.

Another device which might be used as an eliminator is mentioned by Mr. Mosteller and is shown in Fig. 15.

After having studied a good many reports of test work, including some of the reports just discussed, L. K. Spink (24) has concluded that meter measurement accuracy may be improved by the following:

(*a*) Operating at a higher differential, i.e., in a multiple-



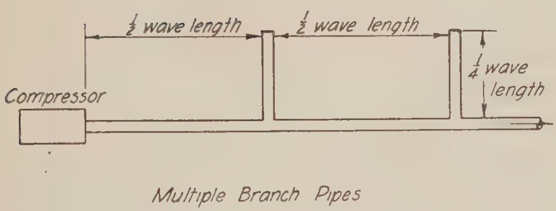


FIG. 15 ELIMINATORS CONSISTING OF BRANCH PIPES

meter run, shutting off one or more runs; or installing a smaller orifice in an existing meter run.

(b) Installing a higher range differential gage and changing operating conditions in order to use the increased range.

(c) Reducing the pipe-run diameter so as to use a higher orifice-to-pipe diameter ratio, still operating at differentials as high as practicable. Increasing the ratio of the orifice diameter to pipe-run diameter will reduce the pulsation error if the differential remains constant.

(d) Installing mufflers, headers, restrictions, or combinations of capacity and pressure drop between primary device and source of pulsation to reduce pulsation amplitude.

(e) Locating the primary device at a point where the pulsation amplitude is lower (as on the suction side of compressors).

MEASUREMENT OF PULSATION

Because of the fact that so many variables enter into an equation for pulsating error and because each installation has peculiarities of its own, computation of the error due to pulsation is out of the question. It is therefore necessary to have some instrument to determine the presence and extent of the pulsation error.

A second electrical instrument suggested by S. R. Beitler using piezoelectric crystals was developed in which the amplitude of the pulsation wave was measured by an indicating voltmeter mounted on top of a small box containing the diaphragm holders, the amplifier, and the mixing switch, so that the entire apparatus was self-contained. The power for amplification was supplied by dry cells so that the apparatus was portable. This instrument was also developed and manufactured by the Brush Development Corporation. Operating experience indicated that there was some question about the calibration of the electrical apparatus and, because of its sensitivity to pressure variations, it was extremely difficult to obtain a representative reading. A mechanical device which gives the amplitude of the differential-pulsation waves has been developed by S. R. Beitler (25) and J. E. Overbeck. This device, shown diagrammatically in Fig. 16, is a variation of the indicator and has proved very satisfactory in operation.

In its present form the mechanical pulsometer consists of two cylindrical volumes, A and B, Fig. 16, separated by a sylphon

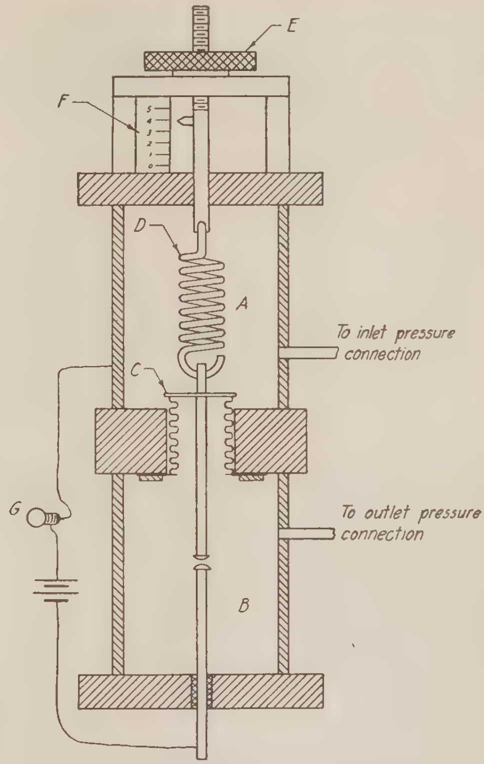

FIG. 16 MECHANICAL PULSOMETER

bellows C so that there will be no leakage between the two volumes which are connected to the inlet and outlet pressure connections of the meter, and as close to the primary element as possible. A coil spring D is mounted in volume A, which volume is connected to the high-pressure tap. The tension on this spring can be changed by turning the handwheel E which is outside the instrument. The scale F (each division represents $^1/_{10}$ in.) indicates the elongation of the spring. Electrical connections are arranged in volume B, which is connected to the low-pressure tap, so that any motion of the bellows caused by differential pressure will be indicated by a light G located on the outside of the instrument. During operation the tension of the spring is gradually increased until the light goes out. This indicates that the differential pressure has been equalized by the spring tension. When this occurs the tension of the spring should represent the differential pressure due to the flow plus the maximum amplitude of the differential pressures.

The instrument spring can be calibrated by comparing its scale readings with any differential gage when connected to a set-up where there are no pulsations present. When measuring pulsation amplitude the instrument is almost totally unaffected by inertia, since the moving parts are practically at rest when the determination is made.

To determine the correlation between pulsometer reading, meter differential, and meter error a research project was sponsored by the American Gas Association and The American Society of Mechanical Engineers. A special test station, shown diagrammatically in Fig. 17, was constructed near Sugar Grove, Ohio, at the Crawford No. 2 Station of the Ohio Fuel Gas Company. (It was the good fortune of the author to be a member of the research working committee during the period that many of

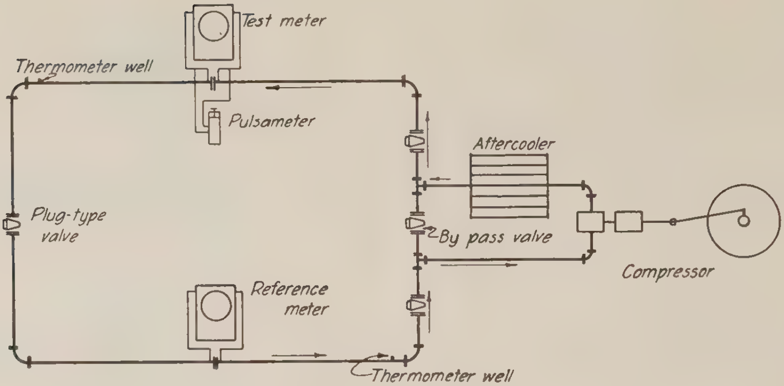

Fig. 17 Arrangement of Pulsation Test Piping
(Crawford No. 2, Sugar Grove, Ohio.)

the tests were conducted.) This test station was built with two orifice meters in series, one on the discharge and the other on the suction line of a large gas compressor. Gas was supplied to the first orifice directly from the outlet of the aftercooler of one compressor, and after passing through the second orifice meter, was discharged back into the suction of the same compressor.

With this arrangement pulsation could be maintained as nearly constant as possible and the other measured conditions could be easily changed to give the pressures and rates of flow desired. Throttle valves (plug-type valves) were placed in the line between the two meters and also between the compressor and the inlet and outlet of the test setting. By means of these valves it was possible to regulate the pressure on either one of the meters so that it would not be subjected either to suction or discharge pulsations from the compressor.

This meter was then used as a standard or reference meter and the measurement error due to pulsation was determined by comparing the quantity indicated by the meter subjected to pulsation (or test meter) against that indicated by the reference meter. The test meter was equipped with both "flange" and "pipe" taps, and readings were taken on both simultaneously in order to determine what effect the location of pressure taps might have on the test results.

In order to eliminate the effect of small variations in orifice plates and runway construction, so-called "unity tests" were run for each arrangement of orifice plates. In making these tests the flow into and out of the setting was throttled to the extent that there was no pulsation on either meter. By comparing the quantities as measured by the two meters under these conditions, an indication was obtained of how close the meters would check each other when no pulsation was present.

As shown in Fig. 17, the setup is as it was arranged for the determination of discharge pulsation. When the study was made on the effect of suction pulsation the function of the meters was interchanged and the pulsometer was moved to the other meter.

Since changing the speed of the compressor would change the type of pulsation, a by-pass was built into the setting between the inlet and outlet so that it was not necessary to change the speed of the compressor in order to change the rate of flow through the setting. The compressor used was a two-cylinder double-acting Ingersoll-Rand machine having $18^1/_2$-in. × 48-in. cylinders and operating at approximately 70 rpm.

The curve shown in Fig. 18 was determined from the tests at this station. In preparing this curve the results of about 500 tests on orifices with diameter ratios of from 20 per cent to 80 per cent in 2-in., 4-in., and 6-in. lines were studied. It was decided not to attempt to determine any correction factors but to concentrate on the determination of the conditions under which meters would measure accurately. Taking many facts into consideration, it was decided that a meter, subject to pulsation, would be normally within the limits of commercial accuracy when the error was less than 1 per cent. Taking into account spot tests made with commercial setups and recording gages, it was felt that the probable accuracy of any individual test not subject to pulsation was within the range of ±0.5 per cent.

All of the test points were plotted on a large sheet, and the percentage of error was marked on the points. The line was then drawn through the points where the error was approximately 1.5 per cent. Because of the inherent limitations on the accuracy of the tests there were three or four points with an error greater than 1.5 per cent below the curve and ten or twelve points with less than 1 per cent error above the curve. It will be

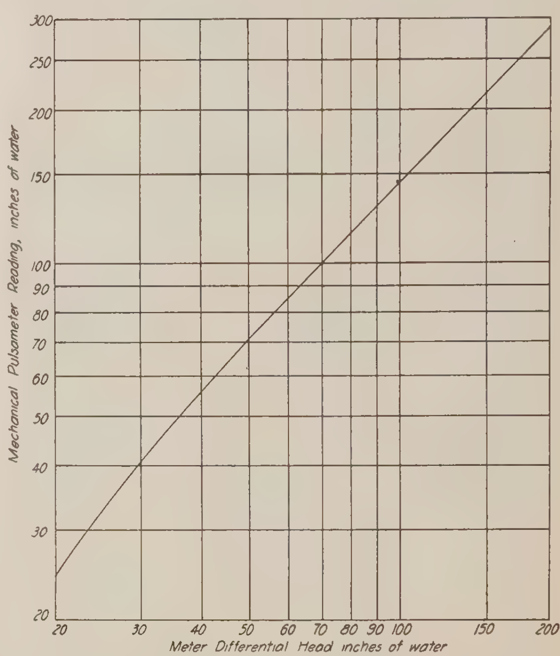

Fig. 18 Relationship Between Meter Differential and Pulsometer Reading for One Per Cent Error

noted that the same curve applies to both flange and pipe taps.

This curve can then be used to determine whether or not a meter measuring pulsation flow is accurate. It is necessary only to attach the pulsometer to the pressure taps and take a reading on it at the same time that the differential pressure is determined. The calibration curve is then consulted to find the pulsometer reading in inches of water. If the point, when plotted in Fig. 18, falls below the curve, then the pulsation error is less than 1 per cent and the meter is probably within the range of ordinary commercial accuracy. If the point falls above the curve, then the pulsation error is greater than 1 per cent, and the measurement with the meter will not be accurate.

For differential pressures less than 32 in. of water the experimental curve was intentionally curved downward at the lower readings, since operating experience has shown that measurements made at low differentials when the flow is pulsating, are very sensitive to changes in pulsation, and it was felt that the line should be lower than normal to allow the effect of these accidental variations. Because of erratic results the empirical curve was not drawn for differentials below 20 in. of water and if pulsations are present, it is believed better not to attempt to meter the flow where the differentials are as low as that. These curves were plotted on logarithmic paper so that points with the same percentage of error would be approximately the same distance from the curve for any value of the differential head.

In order to make use of the available test results all pulsometers must have the same general dimensions as the one used to determine the effect of pulsation, since the shape and dimensions will undoubtedly have some effect on the instrument reading. This pulsometer is patented and is now being built by the Refinery Supply Company, Tulsa, Okla.

As previously mentioned, the location of the curve drawn in Fig. 18 was determined by experiment, and it was thought that the results might be better understood if there was a rational explanation for drawing it in this manner. In order to see the relationship of the empirical curve to some theoretical curves, Fig. 19 was plotted.

Equations developed in the second section, "Mathematical Analysis," were used in obtaining these curves. Values of the error were found for several values of p/h. Then p/h was plotted against the meter error for each wave form, and the value of p/h for 1 per cent error for each of the three wave forms was determined from the curves. Then a relationship was set up between the pulsometer reading $(p + h)$ and the meter differential (h).

In comparing the theoretical curves with the empirical curve it has been assumed that the pulsometer reading is the sum of the differential plus the amplitude of the pulsation. These curves are all drawn for 1 per cent error. It will be seen that there is a reasonable degree of relationship between the empirical and theoretical curves.

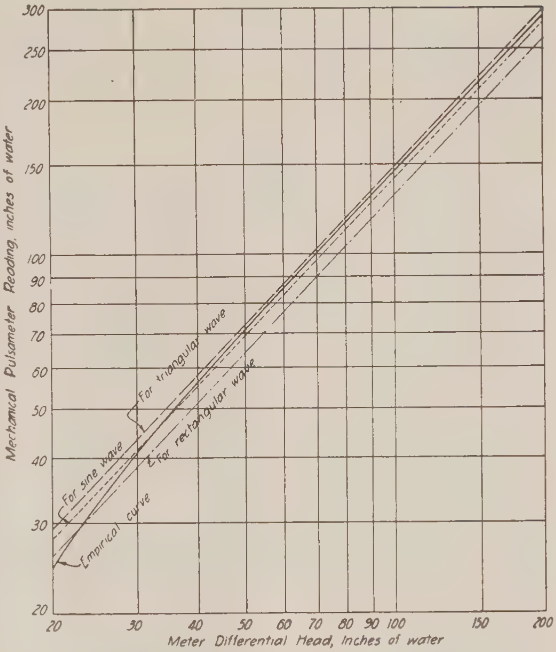

Fig. 19 Theoretical and Empirical Curves for One Per Cent Error

Research to Be Done

Although pulsation has received considerable thought and attention for a number of years and although devices have been built which indicate the presence and others which to a degree indicate the magnitude of the pulsation, considerable work remains to be done.

No use of the pulsometer shown in Fig. 14 has been made in connection with a vapor having pulsating flow. Just how the instrument would behave if the volumes on both sides of the bellows or if the lines leading to the instrument were filled with a liquid remains to be learned through an investigation. At the present time it also seems quite necessary that an instrument be developed for use with meters having low differentials, say, 30 in. and less. The curve now used, Fig. 18, cannot be used with such low differentials with any degree of confidence.

It is also felt that more of a study of the pulsation theory should be made. Heretofore, pulsation produced by a commercial machine has usually been studied. It would seem to be logical to make a laboratory study of pulsations which could be carefully controlled and varied. In this way the degree of error produced by different devices and with different wave forms could be determined.

The studies mentioned are only a few which need to be made. There are, in fact, many others of equal importance.

Discussion

J. E. Overbeck.[4] The writer has had the good fortune of working on some of the research studies explained, as well as of using some of these research data in practical applications.

If the operating gas-measurement engineers will take full advantage of the information now available, which is set forth in this paper, there is certainly much to be gained. In putting these data to practical application, the first step should be to make a study of all measuring stations to determine which are liable to be affected by pulsation. This can be done by reviewing all stations and determining which ones are located adjacent to compressor stations. The term "adjacent" may mean that the meters are located on the compressor-station lot, or it may mean that they may be up to 20 miles away from the compressor station where there is very little pressure drop or resistance between the measuring station and the compressor station.

[4] Columbia Engineering Corporation, Columbus, Ohio.

Each station suspected should be checked with a mechanical-type pulsometer of the type shown in the author's Fig. 16, to determine whether or not the effect of pulsation is sufficient to cause an error in measurement. Such tests should be made under all of the operating conditions encountered, including rates of flow, number of compressors being operated, lines and connections being used, whether or not the gas is passing through scrubbers, coolers, dehydrators, etc. Generally, the pulsation effect will be the greatest with the least number of compressors being operated and with the least number of connections, etc. It is probable that these tests will eliminate a high percentage of the stations suspected, that is, the effect of pulsation will be within the limits as shown by the author's graph, Fig. 18.

Where the effect of pulsation exceeds these limits and is to be reduced, local conditions surrounding the meter stations are big factors, and which method to use, of course, will depend upon these local conditions. In many instances it may only be necessary to change operating conditions or make only slight changes in the equipment, such as changing orifice size, operating at higher differentials, etc.

From the operating standpoint, the charts shown in Fig. 6 and Fig. 7 of the paper, are helpful in determining whether or not to change the meter differential or change the orifice-to-pipe diameter ratio to obtain the most efficient results. For example, where it is not necessary or practical to change the pipe-run size, it will be found that it is more effective to operate at the highest differential, even though flow conditions require a slightly lower orifice-to-pipe diameter ratio.

For those stations where the pulsation effect is beyond the limits, as shown in Fig. 18, the suggested remedies pointed out by the author will certainly be helpful in reducing the error. Many other types of pulsation dampers have been used. Generally, any change in piping that will, through interference, break up the pulsation waves at the point of measurement will increase the frequency, lower the amplitude, and thus reduce the meter error.

It may be found necessary at some stations to make more than one change, that is, increase the orifice-to-pipe diameter, increase the operating differential range and install some pulsation dampers, or change the arrangement of piping between the source of pulsation and meter.

Author's Closure

The comments by Mr. Overbeck relative to checking and correcting meter installations for pulsation are a valuable addition to the paper.

The author feels certain that there are many others who have something to offer which will shed more light on pulsation. There should be several who have tried eliminators besides the ones shown. There should also be additional references. No doubt the theory of pulsation as given in the paper can be expanded.

The author will appreciate receiving any information on pulsation that any reader may have.

Boiler Design for Extreme Load Variations

By M. H. KUHNER,[1] WORCESTER, MASS.

A summation of required design provisions for boilers adapted to operate under quick demand changes. Reference is made to the quick-pickup boiler in the Harbor Steam Plant of the City of Los Angeles and the steel-mill boiler at the Homestead Works of the Carnegie-Illinois Steel Corporation. The importance of water storage, unrestricted path for water and steam in circulation, steam release with minimum disturbance of water body in drum, steam-temperature control during unbalanced firing, and the effect of each item on the others, is discussed. Recommendations are made for determining required capacity of fuel-burning equipment and fans in reference to the extent and rapidity of steam-load changes.

MOST boilers in public-utility and industrial plants are called upon to carry reasonably steady steam loads. Changes in steam demand are gradual and are often predicted in sufficient time to permit required preparations for load increases or decreases. Boilers of what can be termed standard design usually give a good account of themselves under this type of service.

There are, however, other steam power plants, both public-utility and industrial, in which standard boilers would be quite unsuited. These are the plants where steam demand is unpredictable and where load changes are instantaneous and extreme. Steam-electric plants which stand by hydroelectric stations come under this category.

An outstanding example in the utility field is the Harbor Steam Plant of the City of Los Angeles, where a single boiler and turbine-generator unit must be prepared to pick up loads at the rate of 50,000 to 60,000 kw within seconds and without previous warning, Fig. 1.[2]

In the industrial field the steam power station of the Homestead Works of the Carnegie-Illinois Steel should be mentioned, Fig. 2. A single boiler and turbine-generator unit feeds steam and power into the lines of the entire system of "Big Steel's" Pittsburgh district. Whenever a deficiency in steam or power develops in any one of the steel-mill units, it must be made up by the Homestead Works Power Station. Instantaneous load-rate changes as great as 250,000 lb of steam per hr and 20,000 kw are quite frequent.

In the design of boilers suitable to serve safely and reliably in a power plant with sudden and extreme load variations, the following major points must be given careful consideration:

1 That portion of heat stored in the boiler which will become available at once for steam formation with reduction in pressure.

2 Path of water and steam through circulatory system.

3 Release of steam formed by flashing in the water body.

4 Control of steam temperature while steam output and firing rate are out of balance.

5 Effect of rapid thermal changes in steam, feedwater, and combustion gas on boiler pressure parts.

6 Methods of firing and capacity of fuel-burning equipment.

7 Selection of mechanical-draft equipment and drives as to type, capacity, and control.

8 Construction of setting enclosure for momentary high internal setting pressures.

9 Automatic equipment for control of firing and flow of fuel, air, gas, and feedwater.

Heat Storage

When the steam-output rate of a boiler increases elevenfold in a matter of 4 or 5 sec, as is the case with the Harbor Steam Plant boiler, it cannot be expected that the firing rate can be made to increase proportionately and at the same time. Response of the automatic control naturally lags because the control receives its primary impulse from steam pressure or steam flow. It takes time for the fans to speed up, for dampers to arrive at the new setting and for increased fuel and air quantities to reach the furnace. During this time lag the boiler is required to perform somewhat like a steam accumulator. Steam delivered over and above that quantity generated by the existing furnace heat input must be produced by flashing, using heat stored in the boiler water. Part of this heat is made available with reduction in boiler pressure. Steam is formed in the body of water contained in drums, tubes, and headers. The greater the weight of water below the working level, the more heat is available for flashing of steam and the smaller will be the pressure loss for a given steam output. To have the highest possible pressure and heat head available at the moment of load pickup, it is advisable to control the drum pressure of the boiler rather than the pressure at the superheater outlet or at the turbine throttle. The difference between the drum pressure existing at the moment of the beginning of the load pickup and the lowest drum pressure permissible for the work to be done determines the steaming rate during accumulator operation, and the maximum permissible time lag between start of high steam output and correspondingly increased furnace heat release.

The example of the Harbor Steam Plant boiler is probably best suited to illustrate the importance of heat storage. A standard boiler unit of 650,000 lb capacity at 1000 psig, 900 F usually contains approximately 2500 cu ft of internal cubical space below the working water level in drums, tubes, and headers. The Harbor boiler has 3500 cu ft. Its hourly steaming rate is between 60,000 and 100,000 lb, while it is under stand-by load. The drum pressure is maintained at 1040 psig. It can be assumed that during the low steaming rate of stand-by operation the space below the water line is occupied by substantially solid water, that is, water almost free of steam bubbles. The turbine is constructed so that the peak generating capacity can be maintained with 840 psig throttle pressure. Maximum pressure drop through the superheater, steam-temperature control system, and steam line from boiler to turbine, is approximately 100 psi. The boiler-drum pressure may therefore be permitted to drop 100 psi during accumulator operation before capacity power output of the plant is impaired.

Saturated water totaling 3500 cu ft at 1048 psig, which is the mean pressure between water level and lowest point of the system, equals 160,000 lb. It contains 551.9 Btu per lb, or a total of

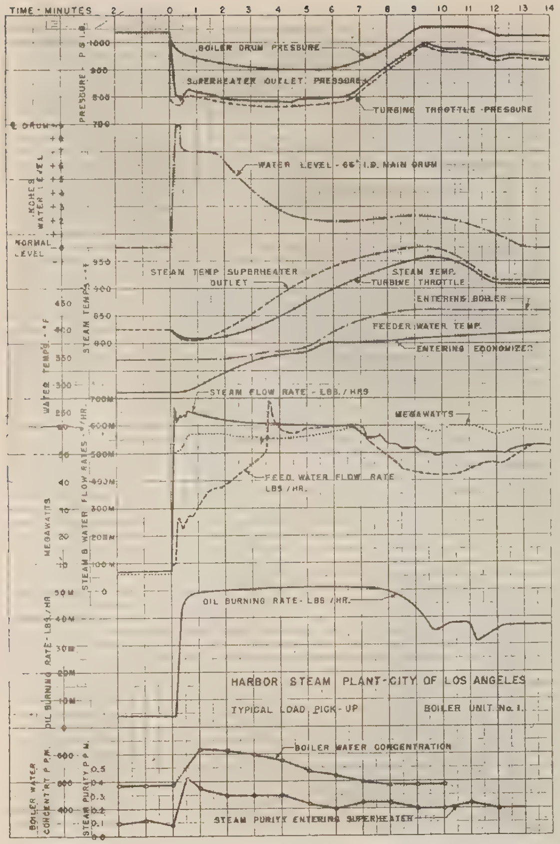
(Steam-output rates change rapidly between 200,000 and 450,000 lb. Fuel is blast-furnace gas and pulverized coal. Steam temperature automatically controlled by heat-exchanger-type control.)



RILEY STOKER CORP

Fig. 3 Performance Data of Harbor Boiler Recorded During Typical Steam-Load Pickup From 70,000 Lb Stand-By Rate, to Approximately 650,000 Lb Per Hr

88,200,000 Btu. If the mean pressure is 100 psi lower, or 948 psig, each pound of water contains 537 Btu and the total heat in 160,000 lb of water is 85,900,000 Btu. The difference, 2,300,000, is available as heat to be flashed into steam.

The heat of evaporation at the mean pressure between the initial drum pressure (1040 psig) and the pressure at the end of the accumulator cycle (940 psig) is 648.5 Btu per lb; 2,300,000 divided by 648.5 = 3550 lb of steam can thus be flashed from boiler water.

The Harbor boiler must deliver steam at the rate of approximately 650,000 lb per hr to develop 55,000 kw output under rapid pickup conditions. The firing rate is established to produce only approximately 60,000 lb per hr prior to the moment the load rise begins. The difference at the rate of 590,000 lb per hr must be made up by flashed steam. A steaming rate of 590,000 lb per hr is 164 lb per sec; 3550 divided by 164 is 22; therefore the heat stored in the boiler water permits the maintenance of 650,000 lb per hr steam-output rate for only 22 sec duration if the firing rate corresponding to 60,000 lb steaming rate is maintained. The boiler-drum pressure will drop from 1040 psig to 940 psig during this period. The 22-sec time lag is usually sufficient for the fuel-burning rate to increase and to meet the new steam-output rate, Fig. 3.

Circulatory System

While the design for unidirectional circulation of water and steam is a basic requirement for all water-tube boilers, it becomes much more important where boilers are subjected to rapid load variations. Not only must the design of the system insure that there can be no stoppage or reversal of flow in any of the steaming tubes during a quick load change, but the path of water and steam must be easy and direct. Abrupt changes in internal cross-sectional area within the circulatory system must be avoided.

A sudden change in steam-output rate results in a momentary disturbance of the flow of water and steam in circulation. If the load suddenly rises with a resulting drop in drum pressure, steam is formed in the entire body of water contained in steaming tubes as well as in downflow and feeder tubes, wherever the water temperature corresponds with steaming temperature. The buoyancy of the steam globules formed in the downflow column opposes the downflow of solid water. The rate of circulation is naturally low during low rates of evaporation. If there are restrictions and obstructions placed in the path of natural circulation, a quick load rise will certainly produce stoppage and reversal of flow in some steaming tubes. This may lead to tube failures. If, on the other hand, the circulatory system is designed so that water and steam can find no serious obstruction in their path, full use can be made of the flywheel effect of the mass of water in motion.

It is calculated that the average circulating velocity of water in the Harbor boiler is approximately 2 fps during 60,000 lb per hr evaporation. The momentum of 80 tons of water traveling at this velocity is an effective force opposing the buoyancy of steam flashed in the water during a load pickup. It assures that unidirectional flow is maintained in all tubes. This boiler has been subjected to a number of rapid load pickups during the past 3 years. The performance recorded by curves, Fig. 3, is typical for such surges. No circulation difficulties were detected.

Steam Release

Releasing the steam generated in the open drum space of the main boiler drum above the water level prevents geysering and turbulence of the water body in the drum and seesawing of the water level. In general, this method effects rapid separation of steam from water. A design incorporating this provision is an advantage for all boilers regardless of type and service.[3]

Rapid steam-load changes are accompanied by water-level variations because the steam formed in the body of water during a sudden load rise, not paralleled by corresponding increase in heat input, tends to lift the water level. The volume of the fluid below the water level increases in direct proportion to the volume of steam formed in the water body. Conversely, a sudden reduction in load, accompanied by a slight rise in boiler pressure, causes steam globules already formed, to collapse, resulting in a shrinkage of the volume below the water line and a drop in water level.

It is important therefore that the drum in which steam is released and in which the working water level is to be maintained, be unusually large. The maximum rise in water level must not reduce steam-release space to the point where there is danger of water carry-over, and the drop in water level must not be such that the entrance to the downflow system becomes exposed and steam, in place of solid water, is permitted to enter the downflow column.

When the drum is equipped with a steam-cleaning and drying device the efficiency of this apparatus is usually dependent upon the height of the water level in the drum. If the level is too high the steam-purifying system may become flooded; if too low, dirty steam and boiler water may by-pass the purifier with disastrous results for superheater and turbine. Because large changes in water-level elevation cannot be prevented during

[3] "How Steam Is Released in Water-Tube Boiler Drums," by Max H. Kuhner, *Power Plant Engineering*, vol. 48, September, 1944, pp. 92–94.

sudden large changes in steam-output rates, it becomes necessary to study carefully the placement of steam-purifying equipment and a larger than normal drum diameter, or a separate steam-purifier drum is indicated.

The Harbor Steam Plant boiler is equipped with a 66-in-ID steam-release drum plus a 36-in-ID steam drum placed above at 14 ft vertical center distance. The volume of water contained in the 66-in-ID drum with the water line at normal elevation is 350 cu ft while the steam space above the water line is 1110 cu ft, Fig. 4. The normal water level is established at 9 in. below the horizontal center line of the 66 in. drum. The water level may rise 11 in. from normal during a load pickup or may drop 6 in. below normal with a sudden steam-load reduction before steam release, steam purification, and water supply to downflow column are affected. The effectiveness of this arrangement is indicated by the steam purity recorded during load pickups. The solids carried away in the steam usually increase momentarily from approximately 0.1 ppm to 0.5 ppm, Fig. 3.

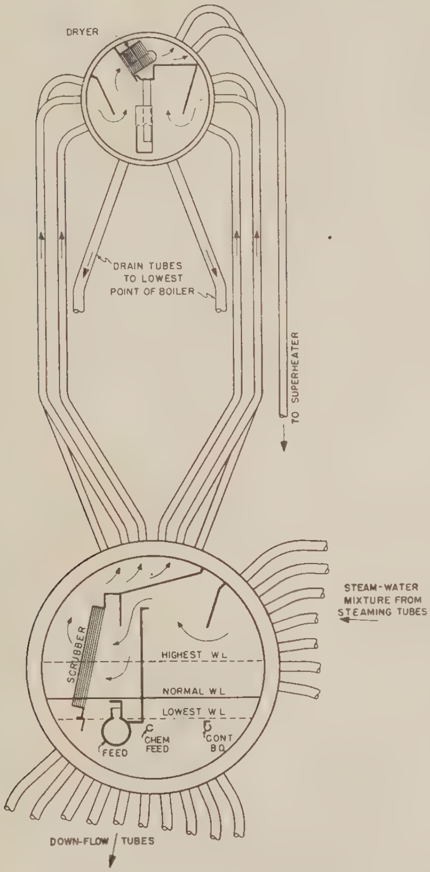


Fig. 4 Steam-Purifying System Harbor Steam Plant Boiler No. 1

Steam-Temperature Control

During normal operation of a central station or industrial boiler final temperature of steam delivered by the superheater is influenced by moisture content of the steam entering the superheater, steaming rate, length of flame, excess air used for combustion, type and kind of fuel, cleanliness of furnace wall and water heating surfaces placed ahead of the superheater, and cleanliness of the superheater surface. These are all factors which can change the steam temperature of an installation. A relatively simple system of steam-temperature control is usually sufficient to produce a workable steam-temperature characteristic in spite of the factors of normal operation mentioned. A system based on control of gas flow over superheater surface or on partial desuperheating is often sufficient to prevent a rise in steam temperature to the point where superheater and turbine are endangered, because each individual factor, or a combination of those mentioned, will not so seriously influence the final steam temperature that the range of a correctly designed control is exceeded.

With a quick-load-pickup boiler additional factors must be considered as affecting steam temperature. During a sudden load rise, and while the firing rate lags 20 to 30 sec behind the increased steam output, very little heat is applied to the superheater surface and a drop in steam temperature must be expected. On the other hand, steam temperature will rise sharply with a sudden drop in steam demand because the firing rate, corresponding with the higher load, continues several seconds after the load decrease has taken place. More heat is therefore applied to the superheater surface than can normally be carried away with the steam. Conditions are aggravated for a purely convection superheater because its normal characteristics produces a steeply rising temperature gradient with increasing steaming rate. A superheater designed so that part of the heat is received by radiation and the remainder by convection, produces a more uniform steam temperature over a wide range in load. Obviously therefore a superheater of this design insures a higher steam temperature at the beginning of the load-pickup cycle, and the effect on steam temperature by the unbalance of steam flow and firing rate at the moment of a sudden load drop is not as pronounced as with the purely convection superheater.

In addition to the points mentioned as affecting superheater performance there is one factor identified with quick-load-pickup boilers only which has a severe effect on steam temperature. Heat removed from boiler water by flashed steam, with the reduction in pressure, must be restored after the high steaming rate is established and while pressure is raised to normal. The fuel-burning rate is therefore not only that required to generate the steam delivered by the boiler, but in addition, that necessary to restore the heat to the boiler water and thus re-establish the normal operating pressure. The heat input to the superheater is considerably greater during the time pressure is being restored

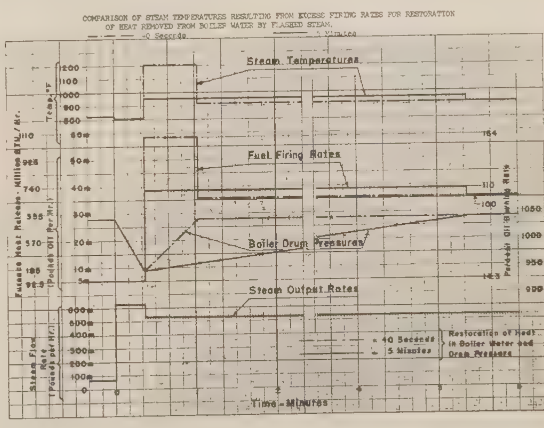

Fig. 5 Comparison of Steam Temperatures Resulting From Excess Firing Rates for Restoration of Heat Removed From Boiler Water by Flashed Steam

than required for normal steam temperature at the existing steam flow. During this period steam-output rate and firing rate are out of balance with the firing rate a considerable percentage greater than needed for the steam output. The result is high steam temperature. The excess rate of firing is, of course, in inverse proportion to the time permitted to restore the heat in the boiler water and to establish normal drum pressure, Fig. 5. The maximum permissible steam temperature usually limits the excess rate of firing and thus controls the time required for restoring normal drum pressure.

Gas by-pass dampers for controlling steam temperature are too sluggish to be effective at the moment of a rapid load increase. The heat-exchanger type of control, or one employing direct-contact water sprays, is more suitable because its action is almost instantaneous if it receives its impulse automatically from the steam temperature, and especially so if the control anticipates a steam-temperature rise by receiving its primary impulse from steam flow.

Thermal Changes

It is apparent that rapid load changes produce rapid temperature changes in feedwater, steam, and combustion gas. Fig. 3 shows that during an instantaneous load pickup by the Harbor Steam Plant unit from 70,000 to approximately 630,000 lb steaming rate, the feedwater temperature rose from 270 to 380 F in less than 6 min, while the steam temperature dropped from 825 F to approximately 800 F in 45 sec, then rose to 975 F in 8 min. The increase in firing rate, from approximately 4000 lb of oil per hr to over 50,000 lb in less than 1 min, naturally produced a rapid rise in the temperature of combustion gas passing over the heating surfaces.

Rolled tube joints and welded pressure connections must be insulated against direct impact of combustion gas to prevent damage from temperature shocks. Feedwater entrance connections must be designed to prevent water of rapidly varying temperature from contacting the drum steel, Fig. 6. The entire pressure system must be suspended in a manner which permits free thermal expansion and contraction without placing unpredictable strains and stresses on pressure parts, setting enclosure, and supporting members.

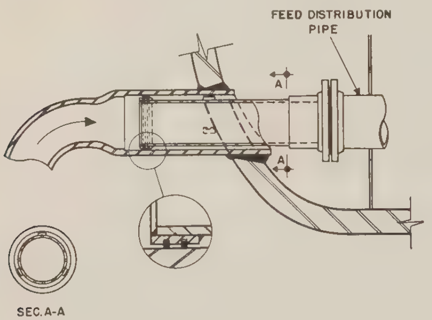

Fig. 6 Boiler-Feed Nozzle

Fuel-Burning Equipment, Type and Capacity

The rapid changes in heat-input rates required by widely varying steam demands call for extremely flexible fuel-burning equipment. Liquid and gaseous fuels are naturally well adapted for this service but burners must be of the wide-load-range type. There is no time for lighting additional burners or for changing burner tips or guns at the moment of load pickup. Neither will the available time permit taking burners out of service or making manual adjustments during a sudden drop in load.

In the case of the Harbor Steam Plant, where oil is the principal fuel, all ten burners are in service at all times. The combined burning rate is only approximately 4000 lb of oil per hr during stand-by operation, but in case of a load pickup the burning rate will have increased to more than 50,000 lb of oil per hr in less than 1 min, Fig. 3. A maximum burning rate of 60,000 lb per hr can be maintained.

Where coal must be burned stokers are usually not suitable because their operating characteristics prevent the required flexibility of heat liberation for quick steam-load changes. Pulverized-coal-firing is better adapted. Although response to load changes is rapid with correctly designed pulverized-coal equipment, the wide range of burner performance easily obtainable with oil and gas is usually not secured. A supplementary fuel, such as gas or oil, may have to assist the maintenance of stable ignition where the load swings to extremely low points.

An outstanding example of this method of operation is the steam-generating unit of the Rankin steam-electric station of the Carnegie-Illinois Steel Corporation, Fig. 2. This unit, of 450,000 lb per hr design capacity, is fired by blast-furnace gas as the main fuel, with pulverized coal to make up any deficiency. Sudden changes in steam demand at the rate of 250,000 lb per hr take place, and because the supply of the blast-furnace-gas fuel cannot be changed as rapidly as necessary to parallel steam demands (whatever quantity of blast-furnace gas remains from other operations in the steel mill must be burned under the boiler), the load swings must be handled by pulverized coal.

The typical steel-mill load of this plant differs from the spinning-reserve service of the Harbor Station. While Harbor receives its high load demands without warning as, for example, in case of a break in the transmission lines coming from the Boulder Dam hydroelectric station, the Rankin plant is usually informed of a major load change a few minutes in advance. If a load pickup is announced, pulverizers are started and remain spinning without coal. As soon as the steam demand exceeds the available supply of blast-furnace gas, raw-coal feeders start delivering coal to the mills, and within a few seconds a pulverized-coal flame is established in the furnace. The pulverized-coal burners contain oil pilots permanently maintaining an oil flame sufficient for instantaneous ignition of the pulverized coal and for support of the flame at extremely low burning rates.[4]

The capacity of fuel-burning equipment for boiler units subjected to extreme steam-load variation must be greater than for a standard boiler installation, because the heat to be released in the furnace immediately following a sudden load increase is not only that necessary to produce the steam actually generated in the boiler, but in addition, that necessary to restore boiler pressure and to replace the heat taken from boiler water while the boiler operated as a steam accumulator. This excess fuel-burning capacity must be determined by the time permissible, or available, starting with the moment of load pickup until full boiler pressure is restored. Fig. 5 shows that in the case of the Harbor Steam Plant unit an excess fuel-burning rate of 64 per cent would be required if it were necessary to restore full boiler pressure in 40 sec, whereas if 5 min were permissible, only approximately 10 per cent excess burning capacity would be necessary. This boiler is actually equipped with 28.5 per cent greater fuel-burning capacity than that required for the continuous steaming rate of 675,000 lb per hr

Mechanical-Draft Equipment

The selection of type, capacity, and driving method of fans is governed to a large extent by the required or desired rapidity and magnitude of steam-load changes for which the installation is designed. The construction of forced- and induced-draft fans must,

[4] "Modern Boilers for Steel Mill Plants," by M. H. Kuhner. *Power*, vol. 87, 1943, pp. 650–657.

in any event, be such that mechanical failures caused by the high stresses produced by the torque required for acceleration are prevented. The drive best suited for the requirements should be selected on the basis of the following considerations:

1 Direct-connected constant-speed alternating-current motors. Gas and air flow controlled by dampers or fan-inlet vanes. Quickest response to load change. High power consumption. High rate of wear and tear of fans and dampers. Operating units for dampers must be extra powerful.

2 Direct-connected variable-speed wound-rotor induction motors. Speed range only 50 per cent of maximum. Dampers required for accurate flow control. Power consumption relatively high, but lower than (1). Slower response to load changes.

3 Constant-speed alternating-current motors with hydraulic or electromagnetic couplings. Power consumption less than (1) and (2). Considerable time required for response to load changes. Dampers required for flow control in low load range.

(4) Direct-connected adjustable-speed direct-current motors, variable-voltage control (or electronic control when available for large motors). Economical power consumption. Quick response to load changes. Speed range corresponding to entire steam-load range. No dampers necessary for flow control. Motor generator set required. High investment cost. (Used with Harbor Steam Plant boiler).

The determination of capacity of mechanical-draft equipment must, of course, be governed by the capacity of the fuel-burning equipment. (Refer to section "Fuel-Burning Equipment, Type and Capacity.")

Boiler Settings

It cannot be expected that ten to twelvefold acceleration of burning rates, often taking place in less than 20 sec, will in every case occur without some disturbance of furnace conditions. In spite of the most carefully adjusted combustion control there is always the possibility that the increased fuel flow reaches the burners a fraction of a second in advance of the corresponding air supply. This may result in a furnace puff or, under severe conditions, in a light furnace explosion. One of the fans may speed up faster than the other, creating momentary high positive or negative pressures in furnace and gas passages.

It is evident that greater than ordinary care must be taken in the design and construction of the setting enclosure and gas and air passages. The setting must be strong enough to withstand minor gas and fuel explosions. It must remain tight under this severe service but it must also be sufficiently flexible to absorb internal shocks and damp them so that they are not transmitted to the supporting structure of the boiler and building. This calls for an entire steel shell enclosing the complete unit, reinforced and supported by a system of steel buckstays and girders which is independent of the main supporting structure. Permanent tightness of the joints of casing panels must be insured by flanges with closely spaced bolts, or by complete welding.[5]

The steel casing of the Harbor boiler is constructed to resist internal pressures up to 100 psf (approximately 19 in. water gage) without noticeable deflection. Air and gas passages are arranged for the most direct flow between furnace and fans.

Control Equipment

A reliable system for automatically controlling firing rate, air and gas flow, steam temperature, and feedwater flow must be in use with boilers operating under extreme load variations. It is impossible to attempt manual control of fuel, air, draft, steam, and water because all adjustments are required simultaneously and in step with the variation in steam demand.

It is not within the scope of this paper to recommend the type of control equipment to be used, but in selecting the equipment it must be kept in mind that the time lag of the control mechanism has a very important effect on the performance of the boiler equipment. The time consumed from the moment the control receives its first impulse of a load change, until the control has repositioned the equipment governing flow of fuel, air, gas, steam, and water, must be as short as mechanical limitations permit. If the response is fast the period during which the boiler must perform as a steam accumulator is short and the reduction in drum pressure is small. In this connection it is desirable to study the design of the equipment to be controlled because speedier response may be obtained by having the apparatus to be controlled designed for the least inertia. For example, multiple-leaf and louver dampers in air and gas passages have less inertia than large single-leaf dampers.

The combustion control receives its primary impulse either from steam pressure or steam flow. Because the time element of response to sudden steam-flow changes should be measured in fractions of a second, an arrangement whereby the primary impulse is received from power demand at the output side of the generator rather than from steam demand at the turbine throttle, might be worthy of consideration. Obviously the control mechanism must be self-compensating to avoid vicious hunting cycles.

It is demonstrated that the water level of a boiler rises sharply during a sudden load increase and drops as fast if the steam-output rate is suddenly reduced. The accumulator performance of a boiler and utilization of heat stored in the boiler water, are discussed in the section "Heat Storage." Keeping these facts in mind, it is readily apparent that it would be quite undesirable to have large quantities of relatively cold feedwater enter the boiler at the moment of a load surge. Cold feedwater would not only reduce the heat available in the boiler water for flashing steam, but would tend to raise the water level still further. On the other hand, the entrance of large quantities of colder feedwater is desirable when it immediately follows a sudden drop in steam demand. The water level is then below normal. Excessive heat in the boiler raises the pressure. Safety valves may start to pop. If there is heavy feedwater flow during this critical time the water level will be promptly restored to normal, and part of the excess heat in the boiler water will be dissipated in the fresh feedwater. It is indicated therefore that feedwater flow should be controlled solely by the working water level if the boiler is subjected to rapid load changes. With feedwater flow so controlled, the entrance of fresh water into the boiler is almost entirely interrupted during a sudden load rise and, conversely, large quantities of fresh feedwater will enter the boiler immediately after a sudden load drop. This action effectively stabilizes the water level and reduces the required distance between highest and lowest working levels.

Conclusion

A thorough analysis of the change taking place in a boiler during sudden and extreme steam-load variations must precede the design of the equipment. Expected magnitude of load swings and time permitted for restoring normal conditions in the boiler must be considered in determining the required volume below normal working level and the necessary capacity of fuel-burning equipment and fans. More time is available for response of control equipment when heat storage in boiler water is liberal, but large-diameter costly water drums and headers are required. A study will show whether large accumulator capacity of the boiler can be justified, or if the use of a more conventional boiler equipped with unusually large firing and fan equipment, and controls of extreme speed of response, is more economical.

[5] "Steel Encased Settings for Modern Steam Generating Units," by Max H. Kuhner, A.S.M.E., unpublished paper No. 716, 1940.

In conclusion it can be mentioned that a large number of the design points discussed as being important for boilers handling extreme load changes are equally desirable for boilers operating under more conventional central-station and industrial loads. Other points become of greater or lesser importance, proportionate to the range and rapidity of load changes. The problem thus narrows down to an intimate study of the plant load cycle, a clear understanding of what happens in a boiler during the expected changes in steam demand, and the solution of each problem thus developed by common-sense design.

Discussion

A. G. Ericson.[6] In this paper the author has capably analyzed and co-ordinated the major design factors to be considered in building a boiler for operation under extreme load variations. The importance of a large heat-storage capacity, made available by substantially increasing the size of the main boiler drum and by increasing the weight of water carried below the working level, is readily appreciated. This feature perhaps marks the essential difference from boilers of standard design and is a fundamental requirement for stable operating conditions. The quantity of heat available for flashing of steam within the allowable pressure drop sets the maximum permissible time lag between start of higher steam output and corresponding increased furnace heat release following rapid load rises. As discussed in the paper, the larger quantity of water circulating also assures that unidirectional flow will be maintained during rapid load pickups, and the larger drum size allows the necessary leeway to offset variations in water level accompanying load swings, preventing water carry-over during load rises and entrance of steam to the downflow columns during load reductions.

Installation of rapid and reliable control equipment is particularly important as the time required for adjusting the burners, damper settings, feedwater flow, and fan speeds results in a heat deficiency that must be supplied by flashing, and extended lags result in proportionately greater steam-boiler temperature and pressure losses.

The author refers to the 450,000-lb per hr boiler in the No. 3 powerhouse at Carrie Furnaces, Rankin, Pa., as an example of a quick-pickup boiler in the industrial field. Although the boiler was designed for this service, the extreme load variations originally contemplated have not developed in actual operation. This powerhouse is the most efficient in the "Monongahela Valley Power System" of the Carnegie-Illinois Steel Corporation and functions as the major generating unit with an average load rating of 85 per cent of rated capacity. Flexibility of operation is essential, for although the operators are informed in advance of general power requirements, there are inevitably some load swings that cannot be foreseen.

Operation of this boiler, described by the author, through load swings of 100,000 lb per hr has been quite satisfactory. Depending upon boiler-operating conditions at the time, the steam pressure will vary up to 50 psi and the steam temperature rarely varies more than 15 deg F. The steam quality remains good and excessive variation in the water-level, geysering, or turbulence of the water body does not occur. Following a decrease in steam load, the temperature of the superheated steam is effectively regulated by a heat-exchanger type of control. This type of control has a slight disadvantage in imposing additional resistance to the flow of steam through the superheater, therefore causing a greater differential between boiler drums and line pressure. However, it is rapid and accurate and the high-temperature element of the superheater is protected against overheating.

In this respect, it may be added that superheat is one of the most important items requiring control in the modern power plant. Excessive steam temperature is likely to cause damage through creep stresses or loss in tensile strength in both the piping and turbine parts. In addition, fluctuation in steam temperature causes opening up of the joints in the high-pressure unit and steam chest of the turbine, resulting ultimately in leaks.

The benefits to be realized from careful and efficient application of the design features discussed in this paper are dependent principally upon the degree of accuracy with which future load cycles are analyzed and power requirements foreseen.

Dan Gutleben.[7] It is refreshing for an operator of a small sugar-refinery steam plant to learn that a condition can arise which requires a public-service plant to give thought to sudden large load fluctuations. Fortunately, the problem submits to logic and arithmetic in the hands of an experienced engineer. The sudden swings were once considered an unavoidable evil visited only upon the sugar-house engineer whose plant was beset with sugar boilers endowed with untold stupidity. The public-service plants, which set the pattern for steam-plant design, accomplished an amazing job and made empirical design facts available to industrial plants long before the bondholders were repaid for the cost of their full-size research. In 1931 when the Pennsylvania Sugar Company in Philadelphia installed two boilers of 250,000-lb per hr capacity and 400 psi pressure, there was a limit to the size of forged drums, besides their cost; and welding had not become available. Accordingly, the boiler designer's talents for meeting the specification of large and sudden swings did not include accumulator operation. That existed only in the good old Scotch marine boiler of revered memory. The design staff (to which the author was attached) answered our clamor for a steam flywheel by providing a six-drum design, two of the drums being on the economizer. The steam-separating drum was forged 51 in. in diam to suit an available mandrel.

Under a premeditated test, with one boiler on base load at 400 psi pressure, the second one was increased in output by 105,000 lb per hr in 2 min with no pressure drop discernible on the gage, and with a rise of 6 in. in the water level. With the thoughtlessness of the sugar-boiler operators this was improved. Early on a Sunday morning, as the demand tapered off, one boiler was shut down and then the boys phoned that the week-end job was complete. Suddenly a large quantity of thin sweet water was found that required to be concentrated and the hour for adjournment was at hand. Without notice, the flowmeter skyrocketed. The steaming rate jumped from 75,000 lb per hr to 225,000 lb. in two minutes, accompanied by a 15-inch spear in the water-level chart. In a public-service plant such a jump in water level would wreck some turbine blades, but in a sugar refinery allowance is made for stupidity, which is a "gift from heaven." Our plant is equipped with a steam accumulator which can provide an instantaneous supply of 40,000 lb of steam for the pans, but this "dinosaur egg" happened to be empty.

H. J. Klotz.[8] The subject of this paper is most timely, as indicated by the recent increase in the number of proposed power-station installations required to operate under wide load variations. The author is to be commended for his logical analysis of the problem and his clear-cut treatment of the various factors which have important influence on the successful operation of equipment under the severe conditions described. In fact, the success achieved in developments such as he has described has en-

[6] Chief Engineer, Homestead Steel Works, Carnegie-Illinois Steel Corporation, Munhall, Pa.

couraged operators, never noted for their backwardness in asking for the impossible, to demand even greater load changes in smaller time intervals. Whereas the Harbor Steam Plant is required to handle a load increase at the rate of about 10 to 1 in a matter of seconds, operating conditions on some utility systems make it desirable to increase the ratio to 20 to 1. The resourcefulness of boiler and other equipment manufacturers, as typified by the work behind this excellent paper, leads the operators to expect that the increased severity of their requirements will be met.

Of the various factors involved, it would seem that all of the features described by the author, with the exception of the fuel-burning facilities, could be expected to be adapted without too great difficulty for the higher ratio of load increase. As pointed out in the paper, only gas and fuel oil are suitable for the minimum rates of firing required by installations of the type under consideration, and where pulverized coal is the basic fuel, supplemental use of the former fuels would be a necessity. A range in firing rates of 20 to 1 is a severe requirement which imposes serious problems in the achievement of a satisfactory design for burning even such flexible fuels as gas and fuel oil. Also, in this connection, a furnace arrangement suitable for stable combustion at the minimum firing rates is of great importance, especially in cases where pulverized coal is to be the basic fuel. Maintenance of stable combustion of course is the factor which prevents pulverized-coal firing from having the required maximum load range without use of supplemental fuel.

C. C. McKee.[9] The author has selected a subject that well deserves considerable attention; especially for those utilities which depend upon hydropower for the major portion or all of their electric supply. Usually in these systems, after installations are complete, the cost of hydropower generation, particularly secondary or dump power, is lower in the hydroplant. For this reason the power produced from steam plants is held at a minimum to reduce fuel cost. Under such circumstances steam plants are required to operate at minimum loads or about enough power to supply all auxiliary drives.

Then when a major disturbance occurs, such as loss of a transmission line, it is necessary for the steam plant to assume full load, without any previous warning, and with automatic controls to bring the steam generator into action, not only to meet all turbine requirements, but also to replace energy lost from the unit by the accumulator action while the automatic controls were bringing combustion and combustion equipment from low load to maximum capacity.

There are points of interest shown in Fig. 3 which are not indicated in the text of the paper. A study of the pressure-drop curves shows there was a slight indication for a return to normal between 30 and 40 sec. This indication was shown to much better advantage when these curves were plotted to a larger scale. The further drop following this point was caused by the feed-heating system going into action at that time. This early increase of feedwater flow has been corrected and a recent test for quick pickup indicates that increased flow of feedwater was delayed for about $1^1/_2$ min after application of load. There was little, if any, secondary pressure drop; however, the load picked up was less than that shown in Fig. 3 by about 5000 kw.

There is no rebuttal to the question that the boiler for such service must be designed to meet the severe demands; but automatic controls must also come in for their share of praise in their ability to be adjusted, timed, and synchronized to bring all steam-generating equipment to overload capacity in less than 25 sec.

Another interesting item which was checked in particular in our recent quick-pickup test is that the temperature of the feedwater entering the economizer was higher than that leaving, by some 10 deg. In the test data obtained for the curves in Fig. 3 the temperature readings for economizer feedwater in and out were read and indicated this condition, but they were considered unreliable. There was a reluctance to show this condition before checking it thoroughly. During the recent test this particular item was checked carefully, with the result that there is no hesitancy in saying that for a period of 2 to $2^1/_2$ min, the temperature of the incoming feedwater is actually higher than the outgoing feedwater from the economizer. Our estimate of the reason for this condition is that it takes about that long to move the cold water through the economizer.

W. C. Rowse.[10] The writer, who is in charge of the Steam Design Section of the Los Angeles Department of Water and Power, set forth the fundamental requirements for a steam plant which must operate in parallel with hydroelectric plants in an article which appeared[11] before the first unit of the Harbor Steam Plant went into operation. In that article it was stated that the plant should have the ability to operate over a wide range of load factors with reasonably good economy and in addition, the ability to pick up full load instantly when floating on the line at a light load, which latter requirement affected the design of the boiler.

In his paper the author clearly sets forth the boiler-design problems and how they were solved, together with the results of the first quick-pickup test with special fast-recording instruments made on October 12, 1944. The writer's discussion of the paper will consist of a brief statement of actual experience in operation.

Following the usual ups and downs incidental to placing a new unit in operation, particularly the first unit of a new plant, by March 1, 1944, the plant settled down to regular operation, except for the 4000-kw house turbine-generator unit which was appropriated by the Federal Government and shipped to Russia. Since that date the plant has been subjected to all kinds of loads from a minimum output of 64,000 lb of steam per hr continuously to a maximum output of 723,000 lb of steam per hr for 1 hr, all under full-automatic control with all burners on and including quite a few cases of quick pickup of load in emergencies. The most publicized of these was the occasion on March 18, 1946, when two airplanes collided, cutting conductors on two circuits from Boulder Dam, thus cutting off 300,000 kw of generating capacity furnishing energy for the total load of 533,000 kw being carried at that time. Although the frequency at the Harbor Steam Plant dropped momentarily to 40 cycles and continued for 10 min at 50 cycles, which shut down the fans three times, the plant picked up 55,000 kw immediately and 75,000 kw within a few minutes and carried this 75,000 kw for 1 hr. The value of the accumulator effect of the boiler was abundantly demonstrated by the ability of the boiler to supply steam even during the fan outages. These fan outages were due partly to the low frequency of energy for auxiliaries which will not occur again because the turbine-driven house generator is now installed, and partly to the setting of the protective thermorelays on the fan drives, which latter has been corrected. Since March 1, 1944, the only unscheduled outages of the steam-generating unit were for three leaks in economizer welds which were repaired over week ends.

An exhaustive test was made of this boiler during the first part of 1944, under the supervision of Mr. Sheppard T. Powell, primarily to check circulation and to recommend boiler-feedwater

[9] Mechanical Engineer, Department of Water and Power, City of Los Angeles, Calif.

[10] Engineer of Steam Design, Department of Water and Power, City of Los Angeles, Calif. Mem. A.S.M.E.

[11] "Some Features of the Harbor Steam Plant of the Los Angeles Bureau of Power and Light," by W. C. Rowse, *Mechanical Engineering*, vol. 64, 1942, pp. 773–776.

treatment and control procedures. At first a total of over 100 readings and analyses were made on each shift. As knowledge of the circulatory and other characteristics of the boiler increased, some of these readings and analyses were discontinued until, after about 6 months, a normal feedwater-control procedure was evolved. One important result of these tests was to demonstrate clearly that the boiler had been properly designed especially as to positive circulation and delivery to the superheater of steam of the required purity.

On April 24, 1946, the installation of the 4000-kw house turbine was completed, and on May 8, 1946, a quick-pickup test was made, with adjustments to the automatic controls which resulted in holding back boiler feedwater longer, and in faster opening of the fuel-oil valve. The method of increasing the load instantly is interesting. One unit at Boulder Dam was loaded with the exact load which the Harbor Steam Plant was to pick up. The 4000-kw turbine-generator unit at the Harbor Steam Plant was carrying the auxiliaries, the main turbine-generator unit was carrying 10,000 kw on the low governor block, the high governor block was set for the load to be picked up and the governor was set for a slightly higher speed than 3600 rpm. When the circuit-breakers at the Boulder unit were opened, the momentary drop in system frequency tripped the low block on the Harbor unit which picked up the load instantly with only a momentary change in system frequency. Although the load picked up (48,000 kw) was not as large as the engineers desired, the results showed a great improvement in every way over the previous test of October 12, 1944. The time required for return to normal conditions was shorter, and the maximum steam temperature lower (only 925 F at turbine throttle) than the previous test. It should be noted that both tests were made under full automatic control.

The over-all efficiency of the plant has been better than the expected efficiency. A Willan's line, in which barrels of oil per month are plotted against kilowatt-hours net output per month, results in a formula of 5250 bbl of oil (6,250,000 Btu per bbl) per month for zero net output plus incremental oil at the rate of 595 kwhr net output per barrel of oil. This results in an over-all efficiency of 11,250 Btu per kwhr net output at rated capacity (62,000 kw net output), as compared with an expected value of 11,400 Btu.

Author's Closure

It is very gratifying to have the correctness of the conclusions reached with this paper verified by the actual performance experiences with quick load pickup boilers reported by Mr. Rowse, Mr. McKee, and Mr. Ericson. These discussers' comments are of specific interest because they point the way to further improvements in steam plants required to operate under unusual load conditions.

Progress in any field is gradual and if the steps forward are not too large the result of the future step can be predicted with reasonable accuracy by the experience with the present. A boiler load increase of 1 to 10 taking place in a few seconds and without trouble was considered quite hazardous only a relatively short time ago. Mr. Klotz mentions the future requirement for load pickups in the ratio of 1 to 20. A safe boiler design for this condition is today entirely feasible if the Harbor Steam Plant experiences are made the basis for this next step.

Mr. Gutleben's reference to the human element in steam plants points to the importance of the correctly designed complete automatic-control system mentioned by Mr. McKee, but the steam-plant operator is well advised not to take the designation "automatic" too literally. Automatic control cannot replace human thought. It is especially important in plants subjected to extreme load variations that the men in charge know intimately the sequence of the various operations normally performed by the controls. The operators must be trained to take over and operate manually in case of failure of the automatic controls. Several of the pickup tests referred to by Mr. Rowse were performed to acquaint the Harbor Plant operators with all that can happen during a bona fide pickup and to instill confidence in the equipment.

The valuable supplementary data and information supplied by the discussers are gratefully acknowledged.

Acid-Cleaning of Boilers and Auxiliary Equipment

By S. T. Powell,[1] Baltimore, Md.

Acid-cleaning of equipment has been demonstrated over a long period as a useful and economical means for removing encrustations from boilers and many other types of power-plant equipment. This paper explains the use of various cleaning reagents and inhibitors, the procedure which should be followed, and the precautions to be taken to safeguard both personnel and equipment from the hazards inherent in the process.

The use of acid to remove deposits from metallic surfaces has been practiced for many years and in widely divergent industries. Such processes have been and still are extensively employed for the removal of mill scale from sheets, plates, tubes, and other products in mills making steel and copper alloys, and enormous quantities of acid are used for such services. The economy and speed gained in removing deposits in this manner have directed attention to many applications, and the treatment has been extended to the cleaning of oil wells, water mains, heat-exchange equipment, boilers, and other equipment. The extensive acidizing of oil wells to improve yields, by removing deposits and opening the formations, did much to attract interest and suggest other applications.

One of the most interesting acidizing projects,[2] which was performed more than 25 years ago, was the cleaning of the entire piping system in The Bankers Trust Building in New York City, a 35-story office building. After 12 years of service the pipe lines throughout the structure were seriously clogged with corrosion products. It was estimated that repiping would cost from $100,000 to $300,000 and could be done only at serious inconvenience to the tenants. Sections of the piping system were cleaned by means of inhibited muriatic acid in about 8 hours, after the offices were closed on Saturdays. It is surprising that this novel method of cleaning pipe lines did not receive more widespread interest at that time since the basic principle of the procedure has much merit. It is obvious that removal of deposits is merely a temporary expedient and must be followed by other forms of corrective treatment to avoid their recurrence.

The removal of scale from boiler surfaces was a logical development after the practical application of acidizing for other uses was demonstrated. The most rapid expansion of this method of boiler cleaning, however, has occurred within the past 4 or 5 years because of the need for reducing boiler outages to a minimum, and because of the shortage of labor during the war period. The effectiveness of acid cleaning is demonstrated in Fig. 1 which shows the heavily encrusted tubes of a chemical evaporator. Fig. 2[3] shows the same evaporator after being cleaned.

Thousands of boilers and miscellaneous equipment units have been cleaned by acid during the last few years and a majority of these treatments have been successful. It is a recognized fact, however, that even though inhibitors may be used, these compounds do not completely prevent corrosion, but merely reduce the rate and extent of the attack. Under ordinary conditions the corrosion of the surfaces is relatively minor if an effective inhibitor is used, if the temperature is satisfactorily controlled, the contact time limited, and subsequent washing out and neutralization of remaining acid properly performed.

Considering the large number of boilers which have been acid-cleaned, there have been only a relatively few cases where noticeable corrosion has taken place; however, there is no accurate record of the extent to which all acid-treated equipment has been corroded. From our personal experience we are inclined to believe that where the temperatures have been properly maintained and if the acid was thoroughly removed from the surfaces after cleaning, the extent of attack has been minor, and repeated acidizing may be undertaken without seriously damaging equipment. The primary object of this paper is to direct attention to the potential possibility of serious damage if the work is performed carelessly and without proper regard to precautionary measures required to insure satisfactory results.

Although acidizing of boilers is most widely practiced in power plants, still there are many other applications in this field. These may be broadly classified as follows:

1 Boilers, economizers, superheaters.
2 Deaerators, vent condensers, and stage heaters.
3 Surface condensers and heat exchangers.
4 Feedwater-treating equipment.
5 Valves and miscellaneous equipment.

Each of these applications requires special study and the treatment must be selected and applied to meet the conditions encountered.

Mechanism of Effect of Inhibitors on Acid Corrosion

There are two general concepts regarding the mechanism by which inhibitors protect steel or other metals when in contact with acid solutions. One group of investigators[4] suggests the following mechanism: Iron goes into solution at the anodic regions, forming ions, while hydrogen is discharged in equivalent amount at the cathodic areas. The cathodic areas occur principally in the narrow spaces of grain boundaries in steel or between the slag and metal in wrought iron. Most inhibitors are bases or positively charged colloids which, when present, travel to the cathodic areas and are deposited and adsorbed on the surface. The electrochemical process is stopped when the reaction at either pole is stifled, and the inhibitor thus retards corrosion. It has also been stated that the presence of the inhibitor raises the hydrogen overvoltage above any potential which can exist in the acid-metal system.

A second explanation is that the inhibiting compounds serve to blanket the entire metal surface by a protective layer of the

organic compound used. This occurs as simple adsorption of the inhibitor ions on the metal surface, through the nitrogen atom which is a component in most organic inhibitors. The stereochemical structure of the inhibitor determines its effectiveness because the structure controls the degree of concentration that will occur.

Others have gone further and contend that inhibiting substances form a nonpermeable blanket through which the hydrogen cannot diffuse and which is limited to the metal surface, as contrasted to the oxide surface.

One investigator has submitted data to show that the action of inhibitors cannot be explained by the electrochemical or overvoltage theory nor by the formation of an impervious pore-free film on the oxide-free metal surface. Test results have been submitted to indicate that inhibitors are adsorbed simultaneously on both metal and oxide surfaces; however, the concentration is heavier on the clean metal surface. The film which forms increases the electrical resistance from liquid to metal, but the film is porous, being built up of molecule aggregates or micelles spaced closely together, similar to a pincushion filled with pins. The theory developed from these studies is that the long-chain molecules thus form long narrow channels similar to capillaries or gel structures. This condition is reflected in reduced diffusion velocity and migration velocity of the hydrogen and sulphate ions which are active in the corrosion of iron in sulphuric acid. The net result is a reduction in the corrosion of the metal, and inasmuch as a more concentrated film is present at the clean metal surface, the oxide is attacked relatively faster than the metal. This results practically in removal of the oxide and preservation of the metal surface.

It has been contended that the corrosion of some boilers during cleaning with inhibited hydrochloric acid is due largely to the formation of ferric chloride which, in itself, is a highly aggressive salt and against which the common inhibitors are not effective. According to this theory the inhibitors will retard the electrochemical reaction involving the displacement of the hydrogen of HCl by iron, but they will not prevent the oxidation-reduction reactions by which ferric chloride oxidizes metallic iron and copper to the ionic form. If metallic copper is in the sludge, ferric chloride attacks it as it does iron, producing cupric chloride which is also an oxidizing agent and a second source of trouble. It is held that the plating out of copper, or its solution to form a chloride, depends upon concentrations of the various ions present.

To limit the concentration of ferric chloride it has been suggested that the solution be constantly circulated and thereby avoid raising the ferric chloride to a level where active attack is possible. There is no assurance that circulation will bring about this desirable condition. If ferric chloride pockets or otherwise concentrates at surfaces and remains in a quiescent or semiquiescent state, it may react more slowly if only diffusion is available to carry away and remove the products of the reactions.

To support the foregoing theory, corrosion has been produced experimentally with dilute solutions of ferric chloride containing no hydrochloric acid except that resulting from hydrolysis.

It should be pointed out that if inhibitors retard corrosion by covering the entire surface and preventing contact with the acid, they should be equally effective against solutions of ferric or cupric chloride. If the impervious-film theory of inhibitor mechanism is correct, any specific vulnerability of the film to certain solutions would seem doubtful, but if the film leaves certain areas exposed, they could be attacked by oxidizing agents in the absence of an opposite electrode reaction. It is a known fact that inhibitors do not give complete protection, and the actual over-all attack which occurs may no doubt be aggravated by oxidizing agents. Whatever the role of ferric chloride and copper may be, it remains true that with proper care equipment can be acidized repeatedly without hazard.

Practical Effect of Acid-Cleaning on Boiler Steel

Studies of metal which has been repeatedly acid-cleaned show that some corrosion occurs each time, but the rate of attack is not sufficiently rapid, generally, even after many cleaning cycles, to cause serious concern. In some instances acidizing has been blamed for active attack on the metal when this treatment has not actually been responsible but has merely revealed the presence of corrosion which occurred previously and passed unnoticed because the pits and surface etching were filled and coated over with iron oxide or encrustations which the acid removed.

The effect of acidizing may be best evaluated by meticulously cleaning the surfaces before the acidizing, either by wire-brushing or local application of weak acid, and inspecting the metal for pitting, under low magnification and with tangential illumination. The same surface should be similarly cleaned and inspected after the entire unit has been acidized. The pitting shows up on stressed metal, hence for these inspections it is best to select the rolled ends of boiler tubes, the heads or nuts of highly strained bolts, the bends of angle irons, welded zones, etc. In most cases such scrupulous before-and-after inspections have not been made owing to the need for returning the equipment to service as quickly as possible after the cleaning has been completed, or because the operators were unaware of what to look for.

It is a well-known fact that the rate of attack on metals by acid or any other electrolyte is greatly affected by the internal stresses in the material. Examination of boilers which showed corrosion after acid-cleaning demonstrated that the most severe attack was on metal which had been greatly stressed. This condition was particularly pronounced on the flared end of tubes where stresses of large magnitude occurred as the result of cold-rolling. This is illustrated in Fig. 3 which shows the "honeycomb" type of attack that is characteristic in units where corrosion developed during acid-cleaning. A photomicrograph of a section of tube which has been attacked by acid is shown in Fig. 4. The honeycomb or lace form of deep pitting is more clearly demonstrated by the photomicrograph. Inspection of numerous boilers has further demonstrated that cold working of the metals used in the fabrication of internal appliances within the drum are also readily attacked by inhibited acid, even when the unstressed metal has shown no corrosion.

Fig. 3 Corrosion Resulting From Acid Attack on Stressed Metal at Flared End of Cold-Rolled Tube
(*A*, This shows honeycomb type of attack.)

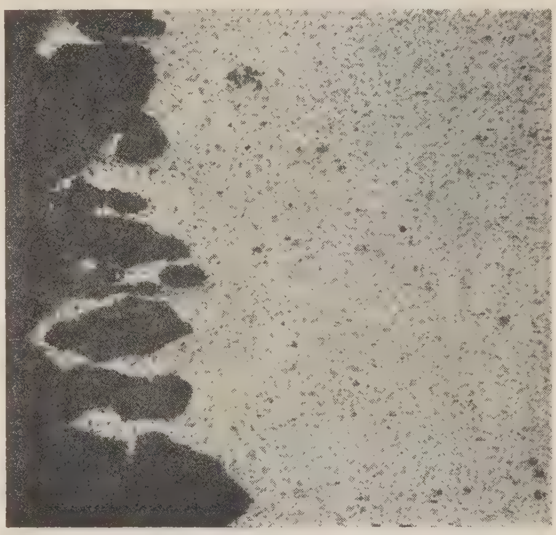

Fig. 4 Photomicrograph of Section of Boiler Tube Taken From Rolled End, Showing Honeycomb Attack During Acid-Cleaning

This type of attack has been observed by the author in a number of installations. Some of the boilers referred to had been acid-cleaned and the temperature of the acid solution was relatively high. In one case the attack was probably due to the effect of an acid contaminant in the feedwater and not to acid-cleaning. The pattern of the corrosion, however, was identical to the type and pattern of attack which was noted in acid-cleaned boilers. This occurrence tends to demonstrate that all corrosion of tube ends may not be the result of acid-cleaning, but may have resulted from some contaminant present in the feedwater. This observation suggests the need for an intensive investigation to determine all conditions which may be responsible for corrosive attack, and the avoidance of unwarranted criticism of acid-cleaning, which in the final analysis may not be responsible.

Some concern has been expressed as to the possible intercrystalline attack on steel due to the penetration of hydrogen into the steel during or subsequent to acid-cleaning. Although relatively large amounts of hydrogen may be generated during the cleaning period, investigations have shown no attack on the intercrystalline structure or any evidence of embrittlement attendant with such form of corrosion. Such investigations have not been extensive, still it seems reasonably safe to predict that embrittlement will not occur if temperature and strength of acid used is within the safe limits, and if the acidized units are thoroughly washed and acid adhering to the surfaces is completely neutralized.

Factors Influencing Effectiveness and Safety of Acidizing Equipment

There are numerous conditions which require control during

acidizing of any equipment in order to insure effective removal of encrustations from the surfaces and a minimum of corrosive attack on the metal. It is not possible to list specifically all of the many conditions which may be encountered, since there are a multitude of variables which may alter the effectiveness of the acidizing process. In general, however, the items which should be considered, and controlled if possible, are as follows:

1 Composition and concentration of acid.

2 Nature and composition of inhibitor.

3 Additional chemicals employed for their wetting, catalytic, or special solvent properties.

4 Temperature of the metal and of the solutions.

5 Circulation, mechanically induced or by diffusion.

6 Composition of the metal.

7 Physical and chemical composition of the scale to be removed.

8 Procedure followed, from taking equipment out of service through removal of acid and washing down and neutralization of acid remaining on the surfaces after treatment.

Time does not permit complete discussion of all the foregoing items, nor would it be appropriate to elaborate on all of them here, since many of them involve complex chemical reactions which are outside the scope of this paper. However, there are certain items in the list which may be profitably discussed as they are of interest to mechanical engineers and others responsible for acidizing of power-plant equipment.

Type and Concentration of Acidizing Solution. It is a common misconception that the cleaning of equipment requires merely the addition of a mineral acid, to which has been added a chemical inhibitor for the purpose of slowing down the rate of attack on metal surfaces. In some cases such treatment may effect the desired results provided temperature control and other conditions are adequately maintained. There are, however, certain types of encrustations occurring in boilers, condensers, and heat exchangers which completely resist solution by muriatic, sulphuric, or other common mineral acids. For instance, the silicate, sulphate and other scales, either alone or combined with other types of encrustations, are not appreciably soluble in muriatic acid. Where such compounds are encountered, hydrofluoric acid or other sources of the fluoride ion must be used to insure their removal.[5] Certain metallic deposits also resist solution, and where such are present, specific solvents must be employed. If oils or greases are encountered, special solvents are necessary for their removal, and effective acidizing results cannot be secured without first removing such materials.[6]

Experience has demonstrated, also, that in addition to the inhibiting chemicals, other compounds improve the effectiveness of the acidizing process. Most of these treatments involve trade secrets, and their use and application are the result and outgrowth of research and development, coupled with practical experience over a wide range of conditions encountered.

The strength of acid to be used should be governed by the time available for cleaning the equipment and the chemical composition of the acidizing solution. In the past the strength of the acid employed has been as high as 15 per cent. Recently, however, there has been a marked trend to the use of acid of lower strength, even though the cleaning takes more time. Concentrations now generally used are from 4 to 7 per cent.

Composition of Inhibitor. The technical literature on the subject of acid-cleaning and pickling of metal contains a long list of organic and inorganic substances which have been used as inhibiting agents to repress the attack on the metal, but which will permit the solution or removal of oxides or other deposits on the surface. A partial list of some of the materials which have been used is shown in Table 1. This list includes only a very small percentage of compounds which are available or have been employed. Actually, there are thousands of organic and inorganic substances which are known to have inhibiting properties. The relative effectiveness of these products varies widely, and they have specific adaptabilities for different services. Most inhibitors are harmless, but others are hazardous and should not be used. In this group are compounds of arsenic, cyanide, and some of the coal-tar by-products. At least one fatality has occurred from the use of an arsenic inhibitor. Operators should be warned against such materials and be informed of their potential danger.

TABLE 1 PARTIAL LIST OF MATERIALS USED OR INVESTIGATED FOR INHIBITING CORROSION OF METALS BY ACIDS

Niter cake	Aniline
Sumac leaves	Pyridine
Formaldehyde	Coal-tar extracts
Glue	Slaughterhouse wastes
Flour	Ethyl iodide
Starch	Paramethylaminophenyl sulphate
Gelatine	Carbozole
Glucose	Cyanide
Thiourea	Quinoline ethiodide
Arsenious oxide	Barium salts

NOTE: The inhibiting effect of the compounds listed, and many other substances, varies greatly as does their cost and availability. Some of these materials possess slight inhibiting value and some are dangerous to use. No inhibitor should be employed without specific information as to its effectiveness and the potential hazard involved in its use.

Practically, the selection of the inhibitor should be left to experts in this field, who should be advised in complete detail about the design of the equipment and the physical and chemical nature of the deposit to be removed. Organic inhibitors are marketed for cleaning operations (such as pickling) which can safely be handled by plant operators. For complex jobs involving major equipment units of the magnitude of boilers and heat exchangers, it is best to rely on the experienced contractor performing the work to select and prepare the acid solution, if the operating personnel in charge of the plant are not informed on the subject.

Temperature. Possibly the most controversial factor with regard to acidizing is the temperature at which the process is carried out, and there is fairly definite evidence that corrosion has occurred in a number of instances where temperatures have been high during cleaning. Many boilers have been cleaned at temperatures ranging from 170 to 180 F, and in one case the temperature was well above the boiling point of the solution and much damage was done. It is a known fact that the inhibiting effect of all chemicals used for retarding corrosion in acid solutions is rapidly reduced as the temperature is elevated. As the result of corrosion of equipment by acidizing at too high temperatures, there is now a trend toward maintaining the temperature of solution during the cleaning period between 140 and 160 F. If sufficient time is allowed for the cleaning, proper removal of the encrustations can ordinarily be effected at the lower temperatures.

In Fig. 5 is shown the extent of corrosion which occurred on the face and edge of caps in waterwall headers. It is probable that the relatively high temperature was responsible for the condition.

Circulation. Various schemes have been used requiring special equipment for applying the cleaning solution to the boiler. In some instances the operators merely inject the chemical into the top drum, while others prepare the solution in a tank and pump it into the boiler and recirculate from the tank back into the boiler. In the final analysis there is not now available sufficient evidence to prove that either circulation of acid by means of a pump, or circulation induced merely by diffusion current is a preferable scheme to use. Both procedures have been followed, in

[5] "Chemical Removal of Scale From Heat-Exchange Equipment," by F. N. Alquist, C. H. Groom, and G. F. Williams, Trans. A.S.M.E., vol. 65, 1943, p. 719.

Fig. 5 Corrosion on Face and Side of Cap Showing Honeycomb Type of Attack

large groups of boilers cleaned, without active corrosion occurring in either case.

Composition of Metal. The composition and the cleanliness of the metal are important factors in resisting or accelerating corrosion during acidizing of equipment. It has been observed repeatedly that low-grade steel containing slag inclusions or other impurities has been readily attacked during acid-cleaning, while the drum and tubes were not affected. In one installation the tops of practically all the acorn nuts used in the fabrication of the internal baffles were destroyed, and a similar condition was noted in a number of other units. To what extent the acid was responsible has not been fully determined, but it undoubtedly accelerated the rate at which the metal was attacked. It is a well-known fact that the material from which such nuts are constructed is low-grade metal, as might be expected, especially during the war years.

Ordinarily, black iron pipe, especially if cold-worked, is readily

(Exact cause for selective corrosion not accurately determined but probably presence of slag inclusions or change in metal structure due to flame-cutting. Note wasting and honeycomb type of attack.)

TABLE 2 TYPES OF DEPOSITS WHICH HAVE BEEN FOUND IN BOILERS, AUXILIARIES, AND MISCELLANEOUS POWER-PLANT EQUIPMENT

Principal ion	Common name	Mineralogical name	Formula determined by x-ray analysis
Group A Boiler and Superheater			
Barium	Barium carbonate	Witherite	$BaCO_3$
	Barium sulphate	Barite	$BaSO_4$
Calcium	Calcium carbonate	Calcite	$\beta CaCO_3$
	Calcium sulphate	Anhydrite	$CaSO_4$
	Calcium sulphate	Hemihydrate	$CaSO_4.0.5H_2O$
	Calcium hydroxide		$Ca(OH)_2$
	Calcium phosphate	Hydroxyapatite	$Ca_{10}(OH)_2(PO_4)_6$
	Calcium phosphate	Whitlockite	$\beta Ca_3P_2O_8$
Magnesium	Magnesium hydroxide	Brucite	$Mg(OH)_2$
Sodium	Sodium sulphate	Thenardite	$Na_2SO_4(V)$
Silicates	Silicon oxide	Quartz	SiO_2
	Sodium-iron-silicate	Acmite	$Na_2O.Fe_2O_3.4SiO_2$
	Sodium-alumina-silicate	Analcite	$Na_2O.Al_2O_3.4SiO_2.2H_2O$
	Sodium-alumina-silicate	Natrolite	$Na_2Al_2Si_3O_{10}.2H_2O$
	Sodium-alumina-silicate	Noselite	$Na_8Al_6Si_6O_{24}.SO_4$
	Sodium-calcium-silicate	Pectolite	$Na_2O.4CaO.6SiO_2.H_2O$
	Calcium silicate	Wollastonite	$\beta CaSiO_3$
	Calcium silicate	Xonotlite	$5CaO_6SiO_2.H_2O$
	Calcium-alumina-silicate	Cancrinite	$4Na_2O.CaO.4Al_2O_3.2CO_29SiO_2.3H_2O$
	Magnesium silicate	Serpentine	$3MgO.2SiO_2.2H_2O$
Iron	Iron oxide	Ferrous oxide	FeO
	Iron oxide	Hematite	Fe_2O_3
	Iron sulphide	Triolite	FeS
Group B Condenser, Evaporator, and Heat Exchanger			
Calcium	Calcium sulphate	Anhydrite	$CaSO_4$
	Calcium sulphate	Gypsum	$CaSO_4.2H_2O$
	Calcium carbonate	Aragonite	$CaCO_3$
	Calcium-sodium-silicate	Pectolite	$4CaO.Na_2O.6SiO_2.H_2O$
	Calcium-magnesium-carbonate	Dolomite	$CaCO_3.MgCO_3$
	Calcium fluoride	Fluorite	CaF_2
Copper	Copper sulphide		CuS
	Copper carbonate	Malachite	$CuCO_3.Cu(OH)_2$
	Copper iron sulphide		$CuFeS$
	Copper oxide	Cuprite	Cu_2O
Magnesium	Magnesium silicate	Forsterite	Mg_2SiO_4
	Magnesium hydroxide		$Mg(OH)_2$
	Magnesium silicate	Serpentine	$3MgO.2SiO_2.2H_2O$
Iron	Iron oxide	Magnetite	Fe_3O_4
	Iron oxide	Goethite	$Fe_2O_3.H_2O$
Sodium	Sodium-aluminum-silicate	Noselite	$Na_8Al_6Si_6O_{24}.SO_4$
Group C Steam and Condensate Line			
Ammonia	Ammonium bicarbonate	Teschemacherite	NH_4HCO_3
Iron	Iron carbonate	Siderite	$FeCO_3$
Sodium	Sodium sulphate		$Na_2SO_4(III)$
Group D Miscellaneous Power Plant Equipment			
Calcium	Calcium carbonate	Calcite	$\beta CaCO_3$
	Calcium carbonate	Aragonite	$\lambda CaCO_3$
	Calcium aluminate		$3CaO.Al_2O_3.6H_2O$
	Calcium phosphate	Phosphate	$Ca_3P_2O_8.H_2O$
Magnesium	Magnesium hydroxide	Brucite	$Mg(OH)_2$
Group E Turbine			
Copper	Copper sulphite	Chalcocite	Cu_2S
Nickel	Nickel oxide	Bunsenite	NiO
Silicates	Silicon oxide	Quartz	SiO_2
	Silicon oxide	Cristobalite	SiO_2
	Silicon oxide	Opal	SiO_2
Sodium	Sodium sulphate	Thenardite	$Na_2SO_4(V)$
	Sodium-carbonate-sulphate	Burkeite	$Na_2CO_3.2Na_2SO_4$
	Sodium chloride	Halite	$NaCl$

attacked by acid even though better grades of metal show no visible attack. The type and extent of the attack are illustrated in Fig. 6. This shows a nipple used as a spacer in the construction of internal baffles in a boiler which had been acid-cleaned. An identical type of corrosion was observed in a number of other units employing the same grade of material.

Corrosion of such parts in boilers or in other equipment is not of major importance and is presented here merely to illustrate the susceptibility to corrosion by acid when the metal in contact with the solution is not metallurgically clean.

Active corrosion occurred on manhole covers in two boilers operating under different conditions. The pattern of the attack is shown in Fig. 7. In one instance it was indicated that the metal may have been fairly hot when the boiler was acidized. In the second case the unit was relatively cold, but the feedwater had been contaminated with an acid compound prior to acidizing. It is believed that the condition of the surface of the metal may have made it more susceptible than other portions of the boiler. These conditions were noted on boilers supplied by different manufacturers.

Composition of Deposits. Table 2[7] shows a number of scales which have deposited in boilers and appurtenant power-plant equipment. Frequently such scale will be composed of several formations, each having specific solution characteristics. Furthermore, the composition and extent of the deposit will vary widely in different positions of the same equipment. This condition is demonstrated by the analysis of the encrustations removed from tubes in two sections of the same unit.

Procedure for Acid-Cleaning Boilers. There is no standardized procedure for acid-cleaning of equipment and no standard solution may be employed. It is obvious that the treatment must be guided and adjusted to meet the many variables encountered. Where the work is performed by a commercial company, the job is taken by contract and the contractor furnishes all the necessary appliances and the material for the complete acidizing, including washing down and neutralizing the residual acid when the cleaning of the equipment has been completed. Generally, it is preferable to have the work done by a trained and experienced contractor rather than to attempt the work by local operators, unless

[7] Acknowledgment is made to Dr. F. N. Alquist, of The Dow Chemical Company, who supplied much of the data included in Table 2.

the necessary trained personnel have been developed who can employ the proper technique for effective cleaning and prevention of the industrial hazard involved in such work.

The program of operation which is usually followed when cleaning boilers consists of the following steps, in the order given:

1 Drain the unit, cool, and inspect.

2 Adjust the temperature of the metal to the desired level by the addition of feedwater.

3 Drain.

4 Fill with inhibited acid.

5 Soak for a predetermined period.

6 Continue tests to determine reduction in strength of acid If concentrations drop rapidly and continue to fall, draining and refilling with the solution may be required.

7 When soaking period is completed, drain the unit.

8 Flush two or three times by pumping feedwater into unit and draining as the pH of the test samples indicates the necessity.

9 When flushing is completed, drain boiler and refill with 1 to 2 per cent solution of alkali (soda ash or caustic soda).

10 Drain, then fill with feedwater above the level in the top drum which was reached by the acid, and then drain to the normal water level.

11 Heat with a slow fire and steam at 10 to 25 psi for 2 hr or more.

12 Empty boiler completely if unit is to be inspected, otherwise lower concentration to desired point by blowing down, furnishing feedwater as required.

Whenever possible, boilers should be drained and inspected after acidizing, and a record kept of the condition of the surfaces for future reference and comparison with conditions observed at subsequent inspections.

There may be many deviations from the foregoing operation, but the general plan is indicative of the steps which should be followed to lessen the danger of corrosion.

Hazards

Since all mineral acids are highly corrosive, especially when concentrated, it is obvious that much care should be exercised to protect both the personnel performing the work and the equipment which is being cleaned. If the treatment is carried out by experienced operators who are cognizant of the dangers involved and take the necessary precautionary measures, the resulting hazards should be negligible Aside from the danger of the corrosive characteristics of the acid, the treatment involves a very definite hazard of fire and explosion if the hydrogen generated is not effectively removed and steps taken to prevent its discharge into the atmosphere. Extreme care should be used, also, to prevent hydrogen from pocketing in any equipment which is being acidized.

How many accidents have occurred from explosions from hydrogen during or subsequent to acidizing is not known but during the past 2 years three accidents of this kind have been reported. In one instance two workmen were killed and extensive damaged resulted from an explosion of a boiler. The accident was caused by failure to vent the gas from the boiler drum, the pocketed hydrogen being ignited by a spark from a flashlight used after the boiler was opened for inspection.

This accident demonstrated the extreme danger of acidizing equipment by persons not thoroughly informed of the reactions which occur when the acid is in contact with steel. The two other accidents reported were also explosions resulting from ignition of accumulated hydrogen gas. These accidents were not fatal to personnel, but resulted in appreciable damage to the equipment.

A number of injuries to personnel, resulting from burning or gassing, have come to the attention of the author. There is one case on record during the past year where an operator cleaning a boiler by inhibited acid was killed by arsenious oxide released by the inhibitor which contained an arsenic compound. This type should never be used, although such inhibitors are quite effective for retarding corrosion.

Conclusions

Experience clearly demonstrates that acid-cleaning of equipment is a useful and economical means for removing encrustations from boilers and many other types of power-plant equipment. However, it should never be undertaken or practiced by inexperienced persons who are not fully aware of the dangers involved. Furthermore, acidizing should be practiced only if and when such treatment is necessary. It is a very questionable procedure for any plant repeatedly to acid-clean equipment as a routine maintenance schedule. Such a program is unwarranted both from the standpoint of cost and over-all depreciation of equipment.

No equipment should be treated with acid unless there is assurance that the acid used can be completely removed after the cleaning process has been completed. Most powerhouse equipment is susceptible to cleaning by flushing and flooding with neutralizing alkaline solutions. However, there are certain appliances that are so constructed that adequate removal of acid cannot be effected, or can be done only with great inconvenience and at appreciable cost. In this group the nondraining superheater is an example of apparatus which does not lend itself to acid-cleaning. In some cases where the superheaters may become badly fouled with deposits which are not water-soluble, acid-cleaning may be practiced. If such work is undertaken it should be attempted only when there is assurance that adequate provision has been made for flushing and neutralization when the work is completed and before the unit is returned to service.

Discussion

F. N. Alquist.[8] The acid-cleaning of boilers and auxiliary equipment has been called to the notice of the Society several times in the past few years. Briefly, attention is directed to a discussion by C. H. Groom, G. Williams, and the writer,[9] on scale removal from heat-exchange equipment. Before this publication and since, we have been working in close contact with the power industry and many others on cleaning problems. The present paper is a valuable contribution to the literature on the subject. Data are also given in a paper by J. L. Wasco and the writer.[10]

Acid-cleaning is an economical method of cleaning power-plant equipment. However, the hazards of the acid-cleaning process should be fully recognized so that only experienced persons will be entrusted with cleaning. All engineers recognize that acidizing should be done only when necessary.

The author's statement, "It is a very questionable procedure for any plant to acid-clean equipment as a routine maintenance schedule," requires further discussion. For example, when should a high-pressure boiler be cleaned? The proper answer is to turbine selected tubes to find the extent of fouling. If the fouling rate thus determined is such that annual cleaning is re-

[8] Organic Research Laboratory, The Dow Chemical Company, Midland, Mich.

[10] "Chemical Removal of Calcium Sulfate Scale," by J. L. Wasco and F. N. Alquist, *Industrial and Engineering Chemistry*, vol. 38, April, 1946, pp. 394–397.

quired, then the plant is acid-cleaned annually on a routine maintenance schedule. These decisions are made by the plant engineers on the basis of cost and over-all depreciation values. The practice of the writer's company on its boilers shows variable times for extent of fouling depending upon water treatments and loads.

It is well that the power industry be made aware of the distinction between corrosion due to operation and corrosion due to improper cleaning procedures. A proper conclusion to be drawn is to maintain treating temperatures as low as possible during cleaning and as stated, preferably between 140 and 160 F.

The author has ably discussed the theories of inhibition. Fifteen years of research by the writer's company on acid inhibitors indicates that both the inhibitor and the acid concentration must be selected so as to give a low corrosion rate under cleaning conditions.

Experience gained on thousands of installations where forced circulation has been compared to circulation by convection, shows that forced circulation is only occasionally necessary.

That the effect of inhibited acid varies as the metals differ in composition has been known in the art for a long time. Power-industry engineers have found that operation corrosion as well as corrosion in cleaning depends upon the composition of the metals involved. Considering Figs. 3, 4, 5, 6, and 7 in the paper, no statement can be made as to how much corrosion is due to operation and how much is due to cleaning.

The steps outlined under procedure for acid-cleaning boilers are good but, under the war-emergency conditions, these steps were not always used because of lack of time; however the engineers of the power industry now follow them more closely.

Finally, the hazards of handling acids and venting the hydrogen that may be produced during the cleaning operation are well known both to the chemical and power industries. With proper safety precautions and helpful papers such as this one, the power industry can take economic advantage of acid-cleaning methods.

R. E. Hall[11] and C. E. Kaufman.[12] We are in agreement with the general facts on acid-cleaning of boilers as developed by the author. More incisive analysis of some of the factors involved brings to light some significant considerations that require emphasis.

Acid used for the process is supplied with an inhibitor, that is, a substance whose purpose is to minimize or prevent attack of the acid on the boiler steel, while not interfering with its dissolving effect on other substances such as the calcium carbonate and phosphate, the iron oxide, etc., comprising the boiler sludge and scale. Concentration of the inhibitor in the acid-cleaning solution is a function of the type of inhibitor used, concentration of acid employed, and temperature at which the job of acid-cleaning is done. Thus one can depend upon the inhibitor to protect against direct attack of the metal by the acid within rather generous temperature limitations, if the concentration of inhibitor required in relation to the acid is consistently maintained, and if the products of reaction of the acid with the boiler sludge or scale are not of themselves potent in their attack on the metal, regardless of the inhibitor.

As a matter of fact, these products of reaction divide into two classes, one of which is innocuous as regards the boiler metal; the other of which is highly aggressive in attack on the metal, even with any usual inhibitor present in the acid solution. Materials which give rise to the first class comprise the calcium and magnesium salts of the boiler sludges and scales; those giving rise to the second class are the iron oxides, either magnetite or hematite. Whether formed in the feed line by the action of dissolved oxygen and thence entering the boiler, or whether formed in the boiler itself by reaction of boiler metal with the bonded oxygen of the boiler water, these oxides represent high oxidizing capacity. Concentrated bit by bit as the boiler is operated and held harmless by the insolubility of the oxides in the boiler water, they await only the trigger action of the acid solution which dissolves them to bring this concentrated oxidizing capacity into play against the boiler metal. Metallic copper, so frequently associated with the iron oxides, may enter into but cannot initiate the oxidation reactions, nor can it contribute thereto. In fact, by plating out on the metal it may even be protective in some measure.

Let us explore conditions in a thin layer of the acid-cleaning solution adjacent to the metal when the sludge or scale consists primarily of insoluble calcium and magnesium salts, and the normally quite low percentage of iron oxide. The acid dissolves the deposit, forming calcium and magnesium chloride, both of which are stable salts devoid of oxidizing capacity. Because of this, they originate no attack on the metal, and the protection provided by the inhibitor in the acid remains intact, unless undue temperature elevation has adversely affected protective conditions. Barring undue temperature, whether flow of the acid-cleaning material over the surfaces is provided for by means of circulating the solution or whether there is or is not considerable agitation of the solution by dissolving such material as carbonate, a protective concentration of the inhibitor in relation to the acid content of the solution prevails at the surfaces.

Let us now explore conditions in the thin film of acid-cleaning solution adjacent to the boiler metal, when the sludge in the boiler is mainly magnetic oxide Fe_3O_4, which dissolves forming ferric and ferrous ions. It is readily demonstrated that the ferric ion is the most important factor in promoting attack.

Fundamentally the aggressiveness of solutions containing ferric ion can be explained on the basis of the following reaction

$$2Fe^{+++} + Fe \longrightarrow 3Fe^{++} \quad [1]$$

It will be noted that this process does not intrinsically involve the disappearance or formation of an acid or a base. Therefore it might be presumed that the inhibitors customarily employed to stifle acid attack on steel would not be well adapted to minimize the reaction of ferric ion with metal. Laboratory tests have confirmed this point.

In the laboratory we have run a number of agitated-solution tests at 150 F, for 6 hr, in which the reality of ferric-ion attack is clearly apparent. For example, when 1 per cent Fe_3O_4 was added to an inhibited acid solution, attack on an inserted steel strip was increased nearly threefold as measured by weight loss. The loss, representing about one third of the potential attack as just defined in Equation [1] was undoubtedly limited by the incomplete solubility of the added iron oxide, behavior which of course may be found in full-scale cleaning operations. When the ferric material was present in considerably greater concentrations and as completely soluble chloride, without acid but with a standard inhibitor present, attack actually considerably exceeded that predicted from reaction [1].

In the removal of deposits from boilers by acid-cleaning, when magnetic iron oxide, for example, goes into the circulating acid, what quantitative potential has it for producing damage? If it is assumed that 1000 gal of cleaning acid builds up to contain homogeneously distributed in solution 1 per cent or 83.3 lb of material originally Fe_3O_4, 20 lb of iron can be dissolved if Reaction [1] goes to completion. If, for example, the dissolution of iron is assumed to take place evenly within 3-in. tubing, the general loss of metal will amount to less than 0.001 in. If, however, the ferric ion is not homogeneously distributed in the acid solution, but rather is selectively concentrated in localized areas

[11] Hall Laboratories, Inc., Pittsburgh, Pa. Mem. A.S.M.E.

[12] Hall Laboratories, Inc.

rich in magnetic oxide, then serious pitting or wastage in such areas may be expected.

Avoidance of such corrosion we believe is best effected by steadily maintained circulation of the acid-cleaning fluid so that localized high concentrations of ferric chloride cannot occur, and by limiting concentration of ferric chloride in the acid-washing solution through adequate blowdown and replenishment of acid solution, thus protecting against too much loss of metal in general corrosion of the surfaces by even the homogeneously distributed ferric chloride which develops mainly at the surfaces or in particular spots in the boiler. Satisfactory control of ferric-ion concentration can be established by analysis.

For the boilers that develop magnetic oxide by the bonded-oxygen process in regions where high heat release renders intolerable any decrease in circulation, acid-cleaning does a specially significant job, in that by cleansing the surfaces of iron oxide, and thus bringing back the original designed circulation in the tubes, the conditions for reaction of the bonded oxygen of the boiler water with the tube metal are minimized. Thus periodic acid-cleaning as required can keep circulation at these points maintained at a level where any formation of iron oxide will be slight, and the boiler will be dependable.

Naturally, acid-cleaning should not be looked upon as something to supplant normal careful procedure in taking care of the boiler. Nevertheless, especially in cases such as those comprised in the circumstances just discussed, it can play a very effective part. Likewise, alkaline-cleaning processes in some instances, dependent upon the composition of material to be removed, are more feasible than acid-cleaning.

No mention has been made of acid-cleaning operations involving nonferrous metals. It would be interesting to know if such cleaning has been conducted and the general types of inhibitors, if any, which proved useful.

L. E. Hankison.[13] This paper is especially valuable because it tells of the dangers that may be encountered, not only to the equipment being cleaned, but also to the personnel engaged in doing the cleaning. The definite warning given by the author that acid-cleaning should never be undertaken or practiced by inexperienced persons who are not fully aware of the dangers involved, should not be ignored. It is evident that this work should be done either by someone commercially in the acid-cleaning field, or by someone who is professionally able to prescribe the proper acid to be used, its strength, the inhibitor to be used, the proper temperature and the length of time for its contact, and then the best way to dispose of the partially spent acid, as well as the proper material and method of neutralizing or removing the residual acid from the equipment. This service presumably can be had only at a cost which must be charged against the benefits that may be obtained by acid-cleaning.

There is another, and probably a much greater cost that must be borne by those who indulge in this means of keeping their equipment in service. It is the loss in efficiency and capacity of the equipment from the time the surface begins to foul until the deposit is of sufficient magnitude to justify removing the equipment from service for acid-cleaning. By using the average between the clean condition and the fully fouled condition as the approximate continuous loss, it can readily be appreciated that this cost is quite considerable and should be avoided if at all possible.

It is our belief that it is much cheaper and very much more satisfactory to secure the services of competent water-conditioning consultants whose aim is to avoid the necessity of any cleaning rather than to acid-clean and bear the costs that have just been outlined. We believe that with this consulting service and properly trained operating personnel to carry out their recommendations, acid-cleaning, or any other type of cleaning that requires equipment outages is unnecessary. Of course, this implies properly designed equipment operated at ratings so that steam pockets, hideout, or reverse circulation is not experienced.

Acid-cleaning has a very important place in power-station operation when the equipment is run at ratings beyond the normal ability of the heat-transfer surface to function. In this case the surface may oxidize or change to form an insulation to a point where overheating and failure will follow. Acid-cleaning may remove the deposit that has been formed and prevent the equipment from failing.

There is another situation where acid-cleaning is beneficial and, in fact, is the only practical means of restoring equipment to serviceable operating condition. During the war, when materials such as condenser tubes and the personnel for their installation were very hard or impossible to obtain, condenser leakage allowed silica to build up in some of our boilers to a point where it was deposited as an incrustation that caused tube failures. Acid-washing restored the boilers to good operating condition, where they have continued to function with the aid of the proper water-conditioning previously mentioned.

One other acid-cleaning experience should be mentioned. Due to water leakage through the packing of the boiler feed pumps into the bearing cavities, it was found difficult to keep oil in the bearing reservoirs. An oil-company representative recommended that the straight mineral oil which had always been used be replaced with a compounded oil that would not float out so easily. This was done and the bearing situation was remedied, but this oil was emulsifiable and such oil as did leave the bearing reservoirs would not separate out in the drip collectors but was carried through into the boilers. There it mixed with the boiler sludge forming a tarry mass containing a small percentage of oil that adhered to the surfaces and caused burnouts. It was thought that increased alkalinity would dissolve this mass but it was not cleared up by this means, so we decided to acid-clean to dissolve the embedded sludge. Acid-cleaning partially dissolved this mass. It also removed much of the protective coating of iron oxide and probably other iron compounds that had been formed on the water surface of the tubes by some reaction of the treating chemical, and which are considered beneficial and desirable.

The presence of this iron compound can be well illustrated by our boiler-gasket experience. Due to scarred or cut hand-hole-seat surfaces, it was considered necessary to use solid copper gaskets to make these parts tight. It was recognized that copper gaskets between the iron or steel surfaces and in the presence of the alkaline boiler water as the electrolyte were not conducive to long gasket life, yet we were never able to find even the slightest attack on these gaskets and they were considered entirely satisfactory. After the boilers were acid-cleaned new gaskets would not last 3 months and we have records of heavy new gaskets practically entirely disappearing in 2 months of operation. This caused us temporarily to abandon copper gaskets. We now believe that the protective coating has been restored by the continued use of treatment, and are trying a few copper gaskets which we hope will again give satisfactory service.

As a further indication that acid-cleaning is detrimental in removing the beneficial iron-compound coating, our experience with corrosive barnacles should be related. After the boilers were acid-cleaned, large quantities of iron-oxide scale were found lodged in the tube headers and also in the tubes that had sluggish circulation. Frequent boiler outages were necessary until all this scale was removed from the system. These outages allowed the internal boiler surfaces to be exposed to atmospheric air, and

[13] Superintendent, Efficiency Department, West Penn Power Company, Pittsburgh, Pa. Mem. A.S.M.E.

small rust spots were formed. These rust spots may have provided the insulation that promoted barnacle growth and boiler-tube failures resulted. This is being given further study. It is now believed that the protective surfaces previously described have been fully restored, as failures of this type have not been experienced during the last $1^1/_2$ years.

While it is agreed that cleaning with acid is beneficial under certain extraordinary conditions, we wish to emphasize the part of the author's conclusion which says, "It is a very questionable procedure for any plant repeatedly to acid-clean equipment as a routine maintenance schedule." We believe that good housekeeping, coupled with intelligent water-conditioning to eliminate the need for acid-cleaning, is the preferred method of operating power-station equipment.

W. R. LaMotte.[14] The writer's company has been particularly interested in the cleaning of boilers by this method. It was first tried in 1939 to clean one of the 350-psi boilers at Kearny generating station. The results were so gratifying, both from the standpoint of low cost and degree of cleanliness obtained, that acid-cleaning has been standard practice at that station ever since. In 1940 the practice was extended to the 1250-psi boilers in the Public Service system. These high-pressure boilers were first acid-cleaned at half yearly intervals, but more recently they have been cleaned annually. As a result, some of them have been cleaned ten and eleven times.

This experience tends to confirm what the author has written concerning the precautionary measures which are advisable in the use of acid for boiler cleaning. The best inhibitor procurable should be used and solution and metal temperature should be kept well below the temperature at which the manufacturer states the inhibitor will break down, the time of contact should be limited, and the various hazards should be recognized and adequate protection provided.

In fact, we differ only with the following statement of the author: "It is a very questionable procedure for any plant repeatedly to acid-clean equipment as a routine maintenance schedule. Such a program is unwarranted both from the standpoint of cost and over-all depreciation of equipment." We look upon acid-cleaning as the normal and best way to clean periodically the internal surfaces of high-pressure boilers. Nothing so far discovered has indicated that measurable harm has been done during the past 5 years.

Perhaps one reason for the foregoing has been the practice of using low acid concentrations, in the range $^1/_2$ to 1 per cent HCl, as contrasted with the range of 4 to 15 per cent discussed by the author. These satisfactory results have been achieved using presently available inhibitors, and certainly improvement in inhibitors can be expected in the future. High-pressure boilers now on order are so designed that the tubes cannot be cleaned by conventional methods; only by the use of liquids can the internal surfaces be reached. It has been our experience that the art of treating the boiler water has not progressed sufficiently to dispense entirely with internal cleaning.

E. L. McDonald.[15] Our company was one of the early users of inhibited acid for cleaning power-plant equipment. For years we have acid-cleaned various heaters, feed lines, pumps, economizers, etc., all under the guidance of the station chemist.

Much was learned from our early experience. For example, do not try to clean old equipment too fast or too well with any scale-removing compound. Scale removed from the tube sheet of a steam-crane boiler by trisodium phosphate exposed loosely rolled tubes and caused a great number of leaks that did not exist when scale covered them. Scale removed from the cast-iron junction boxes of an economizer by acid-cleaning exposed porous spots in the box that did not leak before the removal of scale.

When the shortage of labor during the war first prompted us to employ a commercial acid-cleaning company, we had the idea we could pump the acid to the boiler through the blowoff line which emptied into a sewer at a convenient location for tying-in the acid truck, thus saving the cost of an acid feed line. After a short period of time the acid pumped through the line removed the scale and a great number of leaks developed, which again were not evident when the scale protected them.

All of this is in keeping with the author's statement to the effect that acid is frequently blamed for corrosion which actually existed before the acid was applied and was not evident until the acid removed the scale. The writer has observed corroded surfaces, similar to the type shown in the paper, in boilers and turbine casings that had not been acid-cleaned.

While we have made substantial savings by acid-cleaning with our own crew and equipment, we have not found acid-cleaning of large steam-generating units, as performed by a commercial cleaning company, to be very cheap. The average on five boilers with about 20,000 sq ft of surface each was \$84 per 1000 sq ft of surface. This was about 40 per cent higher than the previous mechanical cleaning cost. On these five boilers a 5 per cent acid solution was used. On three boilers cleaned at a later date, using $3^1/_2$ per cent solution, the cost dropped to \$52 per 1000 sq ft of surface. This was still about 15 per cent higher than the previous mechanical cleaning cost. However, two items definitely favored acid-cleaning, i.e., a shorter boiler outage, and a better job of cleaning. The fact is that it is practically impossible to clean the modern steam-generating unit mechanically.

Mention has been made that the control of acid temperature is important. A thermometer in the acid line can tell a false story. High "spot" temperatures can exist in a boiler if heat is transmitted from brickwork not previously cooled before acid treatment is applied.

The author comments on the possible metal loss due to acid-cleaning; however, it should be remembered the old rotary tube cleaner also removed metal and, before water treatment reached its present stage, more than one boiler tube had to be replaced due to this metal loss. Also, in our own case, we believe the loss of metal, due to corrosion and erosion on the outside of the tube, would exceed any loss of metal on the inside. During acid-cleaning, metal test strips have been hung in boilers, carefully weighed before and after the acid-cleaning, and have given us an idea of the possible metal loss.

Mention is also made of the hazard of generating hydrogen gas when acid-cleaning, and the author comments on a particular boiler explosion. A very serious explosion also occurred last year when acid-cleaning a condenser at the Wichita Station of the Kansas Gas & Electric Company. Details of this are covered in an article by E. D. St. John,[16] which should certainly be read by anybody contemplating acid-cleaning of such equipment.

While acid-cleaning of any equipment has merit, it should not be undertaken except under the guidance of a competent chemist or other competent help.

F. U. Neat.[17] In connection with acid-cleaning, the writer believes that considerably more importance should be attached

[16] "Repairs to Steam Turbine Unit Following Hydrogen Explosion," by E. D. St. John, *Power Plant Engineering*, vol. 50, no. 3, March, 1946, pp. 64–68.

[17] Assistant to Superintendent of Power Production Stations, Consolidated Gas Electric Light & Power Company, Baltimore, Md.

to the possibility of hydrogen embrittlement. Pickling embrittlement is too well known in the steel world to lead us to do anything but go well on the safe side with regard to removing hydrogen. Particularly in the case of boilers, it is quite possible that we may open up crevices in seams and around tubes and these crevices must be stopped. However, if we should permit the rerolling of tubes or calking of joints without making certain the removal of occluded hydrogen, then we are guilty of negligence. The writer's practice is to rinse the boiler thoroughly, after which a solution of 2 to 5 per cent soda ash is boiled in the boiler for 8 to 12 hr at from atmospheric pressure to 50 psi under open vents before the boiler is opened for inspection and certainly before any cold-working of the boiler metal is permitted. This boiling procedure accomplishes reasonable removal of hydrogen gas from the boiler and occluded hydrogen from the metal, largely prevents after-rust, and partially re-establishes the protective coating of magnetic oxide. It may also assist in the loosening of remaining scales which are incompletely soluble in acid.

Attention is also called to a remark by the author which may be misconstrued. In his discussion of the hazards involved he states that the discharge of hydrogen to the atmosphere must be prevented. The writer feels certain that the author really meant that the vents must be piped to the outside in such a manner as to make reasonably sure that discharged hydrogen may not re-enter the building and that these vents be taken from as near the top of the equipment as is possible. If vents are left open during the fill and drain-rinsing operations and then during the boiling-out procedure, we are assured nearly complete removal of hydrogen in the equipment.

H. B. Oatley.[18] Deposits on the heat-transfer surfaces of several types of vessels are very generally recognized by designers as well as users. This is particularly true for vessels or pipe lines conveying liquids at increasingly higher temperatures and pressures.

Attention has been given to the use of purification systems for the removal of these undesirable elements which cause failure of the apparatus. Acid-cleaning has been used with beneficial results by those who, like the author, realize the dangers of such use. The reverse is also true.

The paper has called attention to the outstanding features of this acid treatment and the dangers of such cleaning are clearly and emphatically stated in the author's conclusions.

The increasing severity of operation has brought the designer to the doorstep of the metallurgists for better material, which is to be more highly resistant to deteriorating effects resulting from impeded heat transfer. It may also be said that the chemical industry is looked to by those who require more effective and less dangerous scale-removing methods, entailing the use of chemical inhibitors.

W. F. Ryan.[19] The development of inhibited acids for the cleaning of metal surfaces is just another example of the fact that many of us were born 30 years too soon. When the writer recalls his filthy and laborious efforts to clean boilers and oil coolers in the old 74th Street Station, he wishes that the Dow development engineers had not been so dilatory in the development of acid-cleaning. His successors in the operating field can have these jobs performed with less labor and worry than he experiences when he sends his shirt to the laundry.

In saying less worry, he is not relying entirely on the fact that it may be easier to replace a boiler than to get a new shirt. The author's precautionary remarks are timely and well taken but, on the other hand, the hazards are very slight if one is willing to pay somebody else to worry about them. Most of the adverse experience with which the writer is familiar, has arisen from misguided efforts to save a few dollars by doing the job without experienced supervision or adequate equipment.

In addition to the routine cleaning of boilers, there are special conditions under which the use of acid-cleaning may pay tremendous dividends; for example, in a paper mill it was discovered that the two high-pressure boilers had accumulated an unusual amount of sludge due to changes in the raw-water supply. One tube was blistered and concern was felt for the rest of the heating surfaces. One would not ordinarily think of using acid to remove sludge, but based upon previous experience it was anticipated that a production loss equivalent to one half of the mill's output for at least 7 days would be involved in shutting down the boilers, allowing them to cool sufficiently, cleaning them thoroughly, and getting them back on the line. This was at a time when the mill output was heavily oversold and such a loss of production would be a major catastrophe. Dowell Incorporated was consulted regarding the practicability of using acid in this situation and found that both boilers could be cleaned in a single day. The two boilers were satisfactorily cleaned by circulation of inhibited acid and the entire operation consumed less than 19 hr. The cost of the acid-cleaning was of the order of $500, while the production hours that were gained were worth many thousands.

Another instance of high return on a small investment was experienced in the cleaning of cooling coils in large process tanks. For years these coils which are used with raw hard water, were installed with 3 times the calculated surface in order to compensate for the gradual accumulation of scale. At the end of 2 or 3 years the coils were removed and replaced. The coil itself was not extremely expensive, but the replacement required draining and cleaning the tank with attendant loss of valuable materials. By the use of acid the coil can be cleaned in place with no loss of production or of materials. Life of the coil will be at least equal to that of the tank, and when new tanks are installed the cooling coils can be designed in correct proportion to the demand for heat transfer.

The use of acid-cleaning in power plants and process industries is still in its infancy, with new time-saving and money-saving applications arising every day. Every operating or maintenance engineer who is confronted with the periodic cleaning of metal surfaces should investigate thoroughly what can be accomplished by this method.

H. G. Thielscher.[20] We have acid-cleaned eleven boilers in our plants with satisfactory results. The work has been performed by a commercial chemical company. The strength of the acid solutions used was 5 per cent, the length of time contained in the boilers varied from 5 to 14 hr, and the temperature of the boiler metal and acid solution ranged from 150 F to 190 F. Forced circulation of the solution was not used. We do not know the nature or composition of the inhibitors used as this is considered secret information by the commercial companies. Subsequent examination of these boilers has not revealed any definite evidence of acid corrosion.

Included in the boilers, which were acid-cleaned, was a new 525,000-lb per hr 675-psig 900 F total steam temperature 3-drum boiler, which was acid-cleaned immediately after the conventional boiling and drying-out period. The results obtained were excellent, and an appreciable saving was effected in the time

[20] Mechanical Engineer, Potomac Electric Power Company, Washington, D. C. Mem. A.S.M.E.

and labor ordinarily required to prepare the drums for Apexiorizing. In addition, we believe a more permanent Apexior job was obtained because of the cleanliness of the metal surfaces after acid-cleaning. We expect to continue this practice of acid-cleaning new boilers before they are placed in service. The superheater in this boiler was the vertical nondraining type and was filled with clean warm water before admitting the acid solution to the boiler. In some of our older boilers we had deposits of analcite. The acid-cleaning did not remove these deposits but did soften them up so they were readily removed by turbining.

We agree with the author that there are corrosion and explosion hazards attached to the acid-cleaning of equipment, but, like him, we believe these hazards are negligible when proper procedures and precautions are observed.

G. F. Williams.[21] This paper gives an exceptionally clear picture of chemically removing scales and sludges with acid-base solvents. The author is to be congratulated on this excellent paper which so ably relates the history of acid-cleaning and points out that its effective application involves a careful consideration of all pertinent factors. When one considers the complexity of the questions involved, which deal not only with chemical engineering but also with metallurgy, electrochemistry and other sciences, it is even more apparent that all factors must be carefully weighed by one thoroughly trained and experienced in this line of work in order that the accumulated scale may be removed safely.

It is interesting to note that over 25 years ago the entire piping system of a large building was successfully cleaned of scale by the use of acid-base solvent but, as the author points out, "It is surprising that this novel method of cleaning pipe lines did not receive more widespread interest at that time since the basic principle of the procedure has much merit." Possibly the difficulties experienced on this job were sufficiently serious to deter this type of work in the immediate future and the present commercial use of acid-cleaning may be due in no small degree to the experience gained in using millions of gallons of inhibited acid-base solvents during the last few years for increasing the flow of oil wells.

In only a few cases has any corrosion been noted in boilers following acid-cleaning, and in most of these there was considerable evidence that the corrosion could have taken place during operation of the equipment rather than during the cleaning job. Our company, during the last 10 years, has made over 50,000 separate treatments using inhibited acid-base solvents on oil wells and industrial equipment, and in less than 0.1 per cent of these jobs has any question been raised concerning the possibility of corrosion due to the use of inhibited solvent. In fact, it is the opinion of many operators of large steam-generating equipment that the metal loss from cleaning with acid-base solvents is less than that which results from mechanical cleaning methods.

The manhole cover, shown in Fig. 7 of the paper, showed definite corrosion upon inspection following an acid-cleaning job, but as this unit was not inspected immediately prior to cleaning, there is room for considerable uncertainty as to the cause of the corrosion. Representatives of the writer's company were present with the author and others at the time this inspection was made. Other places on the edges of the manhole covers in this boiler showed occasional large corrosion "pits" much deeper and much larger than anything shown in Fig. 7. It seems practically impossible that such a large amount of metal could have been removed from such a small area in the few hours' time in which acid was in contact with the metal. Probably factors other than cleaning with inhibited acid-base solvent contributed to this corrosion.

[21] Development Engineer, Dowell Incorporated, Tulsa, Okla. Mem. A.S.M.E.

One of the conclusions to this paper, viz., "It is a very questionable procedure for any plant repeatedly to acid-clean equipment as a routine maintenance schedule," might be clarified. Certainly any preconceived schedule for periodical cleaning without any knowledge of the rate at which scale is formed would be questionable, but whenever there is sufficient scale accumulation to warrant its removal, acid-cleaning is the best and sometimes the only feasible way of removing it. After the deposition rate of scale in a boiler is known and therefore the frequency with which it must be removed, it seems entirely reasonable that acid-cleaning could be done on a routine maintenance basis.

Author's Closure

The comments presented on the author's paper by the several discussers are constructive and justify much consideration by those interested in the subject.

The theory on the mechanism of corrosion, as brought out by Messrs. Hall and Kaufman, requires consideration and indicates the need for further research along these lines. Although there is much disagreement among engineers as to the relative merits of circulation to avoid concentration cells, as suggested by Dr. Hall, this is a desirable procedure under some circumstances and, where it can be carried out in a practical manner, circulating the solution may conceivably overcome the tendency to cause spotty corrosion of the metal. Regardless of the advantages offered by circulation during cleaning of apparatus there are many cases, especially those involving cleaning of large boilers designed with complex circuits, where circulating the solution can not be readily affected. It is obvious that uniform circulation through a large unit is difficult and it is doubtful if pumping the solution through units will insure much better movement of the solution over the metal than may be obtained by normal thermal circulation which occurs during the cleaning process.

Regardless of these apparent operating difficulties to carry out the procedures for avoiding corrosion as suggested by Dr. Hall, the problem warrants further study. It is hoped that the Hall Laboratories, Inc., and other interested groups will continue to study and develop means for overcoming many of the troublesome problems encountered in the acid-cleaning technique.

Dr. Alquist's statement that "The effect of inhibited acid varies as the metals differ in composition" has been known in the art for a long time. Power-industry engineers have found that corrosion during operation as well as corrosion in cleaning depends upon the composition of the metals involved. This has not been fully appreciated by many operators. Why some metal corrodes during acid cleaning to a greater extent than others, when the cleaning procedures are practically identical, is not clearly understood but no doubt is related to the composition of the metal and other metallurgical characteristics.

The instructive and informative research now being carried out by The Dow Chemical Company under the guidance of Dr. Alquist and his associates should reveal much valuable information and place acidizing of equipment on a much more exact basis than is now possible with our limited knowledge. It is hoped that this and other organizations carrying on research in this field will release their findings from time to time. Such dissemination of data should serve as an invaluable guide to the profession.

The author is in agreement with many of the comments made by Mr. Hankison, since our experiences have paralleled his regarding a number of difficulties described. The acid attack on copper gaskets during cleaning of boilers has been encountered

many times with varying degrees of severity. These difficulties and other precautionary remarks mentioned by Messrs. Hankison, LaMotte, and MacDonald and the other discussers, demonstrate the need for intelligent planning and control for safe and effective treatment of any equipment by inhibited acid solutions.

With regard to Mr. Neat's comments, namely, "Attention is also called to a remark by the author which may be misconstrued," the author's precautionary remark, of course, related to adequate venting to the outside atmosphere. We regret if our statement in the text has been misconstrued by others. It is presumed to be obvious that the avoidance of a fire or explosion hazard would require complete and adequate venting outside the building by suitable facilities.

The aim and purpose motivating the preparation and presentation of the author's paper was to direct attention to the economic and practical value of acidizing boilers and other auxiliary equipment. The very favorable comments by so many engineers and chemists indicate that designers and operators agree with our viewpoint, differing only in details of application of the process. There are a number of unsolved factors which are not well understood and therefore may not be adequately evaluated. It is hoped that our effort has focused attention on these matters and will stimulate further study of the problem.
